Third, Campbell addressed threats to validity using design features—things a researcher can manipulate to prevent a threat from occurring or to diagnose its presence and impact on study results (Table 1). For example, suppose maturation (normal development over time) is an anticipated threat to validity because it could cause a pretest-posttest change like that attributed to treatment. The inclusion of several consecutive pretests before treatment can indicate whether the rate of maturation before treatment is similar to the rate of change during and after treatment. If so, maturation is a threat. All quasi-experiments are combinations of these design features, chosen to diagnose or rule out threats to validity in a particular context. Campbell was skeptical about adjusting threats statistically after they have already occurred because statistical adjustments require making assumptions that are usually dubious or impossible to test.

Other scholars during this time were also interested in causal inferences in quasi-experiments, particularly

Table 1 Design Elements Used in Constructing Quasi-Experiments**Assignment (Control of assignment strategies to increase group comparability)**

- *Cutoff-Based Assignment.* Controlled assignment to conditions based on one or more fully measured covariates. This yields an unbiased effect estimate.
- *Other Nonrandom Assignment.* Various forms of “haphazard” assignment that sometimes approximate randomization (e.g., alternating assignment in a two-condition quasi-experiment whereby every other unit is assigned to one condition, etc.).
- *Matching and Stratifying.* Efforts to create groups equivalent on observed covariates in ways that are stable, do not lead to regression artifacts, and are correlated with the outcome.

Measurement (Use of measures to learn whether threats to causal inference actually operate)*Posttest Observations*

- *Nonequivalent Dependent Variables.* Measures that are not sensitive to the causal forces of the treatment, but *are* sensitive to all or most of the confounding causal forces that might lead to false conclusions about treatment effects (if such measures show no effect, but the outcome measures do show an effect, the causal inference is bolstered because it is less likely to be due to the confounds).
- *Multiple Substantive Posttests.* Used to assess whether the treatment affects a complex pattern of theoretically predicted outcomes.

Pretest Observations

- *Single Pretest.* A pretreatment measure on the outcome variable, useful to help diagnose selection bias.
- *Retrospective Pretest.* Reconstructed pretests when actual pretests are not feasible—by itself, a very weak design feature, but sometimes better than nothing.
- *Proxy Pretest.* When a true pretest is not feasible, a pretest on a variable correlated with the outcome—often weak by itself.
- *Multiple Pretest Time Points on the Outcome.* Helps reveal pretreatment trends or regression artifacts that might complicate causal inference.
- *Pretests on Independent Samples.* When a pretest is not feasible on the treated sample, one is obtained from a randomly equivalent sample.
- *Complex Predictions Such as Predicted Interaction.* Successfully predicted interactions lend support to causal inference because alternative explanations become less plausible.
- *Measurement of Threats to Internal Validity.* Help diagnose the presence of specific threats to the inference that A caused B, such as whether units actively sought out additional treatments outside the experiment.

Comparison Groups [Selecting comparisons that are “less nonequivalent” or that bracket the treatment group at the pretest(s)]

- *Single Nonequivalent Groups.* Compared to studies without control groups, using a nonequivalent control group helps identify many plausible threats to validity.
- *Multiple Nonequivalent Groups.* Serve several functions. For instance, groups are selected that are as similar as possible to the treated group, but at least one outperforms it initially and at least one underperforms it, thus bracketing the treated group.
- *Cohorts.* Comparison groups chosen from the same institution in a different cycle (e.g., sibling controls in families or last year’s students in schools).
- *Internal (vs. External) Controls.* Plausibly chosen from within the same population (e.g., within the same school rather than from a different school).

Treatment (Manipulations of the treatment to demonstrate that treatment variability affects outcome variability)

- *Removed Treatments.* Shows that an effect diminishes if treatment is removed.
- *Repeated Treatments.* Reintroduces treatments after they have been removed from some group—common in laboratory sciences or where treatments have short-term effects.
- *Switching Replications.* Reverses treatment and control group roles so that one group is the control while the other receives treatment, but the controls receive treatment later while the original treatment group receives no further treatment or has treatment removed.
- *Reversed Treatments.* Provides a conceptually similar treatment that reverses an effect (e.g., reducing access to a computer for some students but increasing access for others).
- *Dosage Variation.* Demonstrates that outcome responds systematically to different levels of treatment.

William G. Cochran in statistics, James J. Heckman in economics, and Sir Austin Bradford Hill in epidemiology. However, Campbell's work was unique for its extensive emphasis on design rather than statistical analysis, its theory of how to evaluate causal inferences, and its sustained development of quasi-experimental theory and method over four decades.

EXAMPLES

In 1966, the Canadian province of Ontario initiated a formal program for the screening and treatment of infants born with phenylketonuria (PKU) to prevent retardation. After the start of the program, 44 infants born with PKU experienced no retardation, and three did. Of these, two were missed by the screening program (Webb et al., 1973). Statistics from prior years suggested a much higher rate of retardation attributable to PKU. Although this study lacked a control group, the authors concluded that the program successfully treated PKU infants. Based on such results, this program was widely adopted in Canada and the United States. This study was a pretest-posttest quasi-experiment with no control group.

In July 1982, Arizona implemented legislation mandating severe penalties for driving while intoxicated; a comparison of monthly results from January 1976 to July 1982 (the control condition) with monthly totals between July 1982 and May 1984 (the treatment condition) found a decrease in traffic fatalities after the new law was implemented. A similar finding occurred in monthly data trends in San Diego after January 1982, when that city implemented a California law that also penalized intoxicated drivers. In a control time series in El Paso, Texas, a city that had no relevant change in its driving laws during this period, monthly fatality trends showed no comparable changes during the months of either January or July 1982. The changes in trends over time in both San Diego and Arizona, compared to the absence of similar trends in El Paso, suggest that the new laws reduced fatalities (West, Hepworth, McCall, & Reich, 1989). This study was an interrupted time-series quasi-experiment.

STATISTICS AND QUASI-EXPERIMENTAL DESIGN

Statisticians such as Paul Holland, Paul Rosenbaum, and Donald Rubin emphasize the need to measure what would have happened to treatment participants

without treatment (the counterfactual) and focus on statistics that can improve estimates of the counterfactual without randomization. A central method uses PROPENSITY SCORES, a predicted probability of group membership obtained from LOGISTIC REGRESSION of actual group membership on predictors of outcome or of how participants got into treatment. MATCHING, stratifying, or covarying on the propensity score can balance nonequivalent groups on those predictors, but those methods cannot balance groups for unobserved variables, so hidden bias may remain. Hence, these statisticians have developed sensitivity analyses to measure how much hidden bias would be necessary to change an effect in important ways.

Economists such as James Heckman and his colleagues have pursued another development, SELECTION BIAS modeling, which aims to remove hidden bias from quasi-experiments by modeling the selection process. Unfortunately, these models have not been very successful in matching results from randomized experiments. Most recently, economists have improved results by combining selection bias models with propensity scores. This topic continues to develop.

A third development is the use of STRUCTURAL EQUATION MODELING (SEM) to study causal relationships in quasi-experiments; this effort has also been only partly successful (Bollen, 1989). The capacity of SEM to model latent variables can sometimes reduce bias caused by unreliability of measurement, but its capacity to generate unbiased effect estimates is hampered by the same lack of knowledge of selection that thwarts selection bias models. A related but newer literature on causality is promising, using directed graphs to help understand the issues (Pearl, 2000).

CONCLUSION

Quasi-experiments are rarely able to provide the confidence about causal inference that randomized experiments can provide, and overreliance on quasi-experiments in some areas is a serious problem. Nevertheless, three important factors have created conditions to improve quasi-experiments. First, extensive practical experience with quasi-experimental designs has provided a database from which we can conduct empirical studies of the theory (Shadish, 2000). Second, after decades of focus on randomized designs, statisticians and economists have turned their attention to improving quasi-experimental designs. Third,

the computer revolution provided both theorists and practitioners with increased capacity to invent and use more sophisticated and computationally intense methods for improving quasi-experiments.

QUESTIONNAIRE

All scientists use “tools” to measure the phenomena of interest to their disciplines, and social scientists are no exception. Thus, just as a telescope serves astronomers and an electron microscope serves microbiologists, the questionnaire serves many social scientists as their primary measurement tool. The challenge to these researchers is to calibrate a questionnaire that will gather data as accurately and efficiently as possible.

From a “total error” perspective, a poorly constructed questionnaire can contribute BIAS and VARIANCE to the data that are gathered (cf. Groves, 1989). In particular, poorly worded, poorly ordered, and/or poorly formatted questions can lead to significant measurement error in the form of both bias and variance, and/or can lead to significant item NONRESPONSE error in the form of bias.

One of the defining characteristics of a questionnaire is whether it is for a SELF-ADMINISTERED survey, as in a mail survey or an INTERNET SURVEY, or whether it is to be *interviewer-administered*, as in a telephone survey or in-person survey. If the questionnaire is self-administered, then the “end user” is the respondent. In these cases, all instructions required to complete the questionnaire accurately must be stated clearly and explicitly within the questionnaire itself. Or, in the case of computerized self-administered questionnaires, instructions can be presented via audio recordings. There are myriad other design features that are affected by whether the questionnaire is self-administered or interviewer-administered; for detailed information, see Dillman (2000).

In creating a particular questionnaire *item*, there are four structural factors to consider: (a) the *question stem* wording; (b) whether the *response option(s)* will be open-end or closed-end; and, if closed-end, whether they are (c) forced-choice and/or (d) balanced. In wording the question stem (i.e., the interrogative being asked), use as few and as simple words possible to convey the meaning of the construct being measured. In operationalizing the construct through this wording, the researcher also must keep in mind the educational level of the respondents. Whenever a questionnaire is self-administered, respondents' literacy must be considered.

Open-end questions allow a respondent to answer in her or his own words and, thereby, provide richer, more detailed responses about what is being measured, especially when administered by an interviewer who can probe for fuller answers in an unbiased and nondirective manner (cf. Fowler & Mangione, 1990). However, open-end responses must be coded before they can be systematically analyzed, and this can be a labor-intensive and costly enterprise to do reliably.

Closed-end responses typically are of a multiple-choice format in which the respondent is provided a series of *exhaustive* and *mutually exclusive* choices from which to choose one. When administered by an interviewer, some closed-end questions have implied response choices, such as “Yes/No” questions. Multiple answers are allowed for some types of questions (e.g., a question that asks about someone’s three favorite leisure time activities). For those interested in the cognitive processes a respondent uses in making sense of a survey question and then deciding how to answer it, see Tourangeau, Rips, and Rasinski (2000).

In designing response options for most closed-end items, the researcher must consider whether the set of choices should contain a “neutral midpoint” and/or an “uncertain” (i.e., “Don’t Know”) response category. Response sets that do not allow the respondent to use a neutral midpoint (e.g., the middle category in the following response set: Agree, *Neither Agree nor Disagree*, Disagree) or do not let a respondent indicate that he or she is “Uncertain” are termed *forced-choice* items. Unforced-choice items are those that provide respondents with an explicit “out,” such as simply indicating he or she is “Undecided.” Choosing which approach to take in wording a survey item should be linked to (a) the phenomenon being measured and (b) respondents’ abilities and willingness to finely differentiate answers (see Krosnick, 1999, for a discussion of “satisficing”).

Another structural consideration in designing a question is whether or not the response scale is balanced or unbalanced. A balanced set of responses has a true midpoint, regardless of whether the midpoint itself is offered as one of the choice. Thus, the response choices of *Strongly Agree*, *Agree*, *Disagree*, or *Strongly Disagree* are balanced even though a true midpoint is not offered explicitly. In contrast, a response set such as *Excellent*, *Good*, *Fair*, or *Poor* is unbalanced because two of the choices are positive, one is neutral, and one is negative.

The order in which questions or blocks of questions are placed within the questionnaire can affect the data that are generated (see Schuman & Presser, 1981). Generally, it is best to organize a questionnaire so that it begins with easy-to-answer, rapport-building items, even if these items will not be analyzed. This reduces the chances of respondents starting the questionnaire, but then quickly refusing to complete it. Next would come items measuring opinions and attitudes, followed by those measuring behaviors and knowledge. The reasoning for this is that answers to behavioral and knowledge questions are thought to be less affected by the order than are opinion and attitudinal questions. The questionnaire should finish with personal background and demographic items. This flow of content within a questionnaire is reasoned to be optimal in minimizing nonresponse, while simultaneously making it less likely that any one type of item will affect answers to subsequent questions.

It is highly recommended that all questionnaires be pilot tested before being used for gathering the actual study data. Pilot testing provides important feedback on how well respondents understand the wording of the questions, on the length of the questionnaire, and on respondent burden. In many cases, it is wise to engage in a round of cognitive interviewing, with one-on-one “think aloud” sessions with pilot respondents who articulate the thinking processes they go through while trying to comprehend and answer each question.

Finally, in devising a questionnaire, the researcher should have a priori plans for data reduction and how to handle MISSING DATA. Data reduction includes the process of using data from several items to create new variables, such as SCALE scores. Missing data are handled in several ways, including statistically imputing a value for each missing datum.

QUEUEING THEORY

Social scientists often study situations in which there is excess demand for some set of limited resources. Queueing theory is a subfield of STOCHASTIC modeling and is the process by which demanders of a specific service or resource are assumed to wait for accommodation. The methodology is widely used in many literatures to describe assembly line-type processes and services in which the completion time is indeterminant. Developed initially to analyze telephone traffic and industrial throughput (Brockmeyer, Halstrom, & Jensen, 1960; Erlang, 1935), it interprets the results from imposing a set of rules that describes three aspects of provision: the manner in which demanders arrive in the system, the capabilities and resources of the supplier, and how individual cases are treated relative to others.

The first component of the model stipulates that transactions arrive stochastically according to an assumed parametric form. Queueing theory models are much easier to describe if we can claim that these arrivals are independent and serial (not arriving simultaneously). It is not required that these transactions stay in the assigned or selected queue until served; they can leave immediately due to queue length (balking), leave after waiting a specified time without being served (reneging), or possibly change to another available queue in the system (jockeying). The parameterized arrivals rate can change with the time index (nonstationarity), or remain fixed over time (stationarity). In addition, different characteristics can be attached to transactions that denote things like priority, complexity, or flags indicating behavior once in the system.

The second major component of the model is a description of the system's servicing resources. Attributes include the number of service queues (or channels), the existence of priority queues, layers of service requirements, and buffering or storage capacity. These features and the way they are arranged determine how efficiently the system can process incoming transactions.

The third and final part of the basic structure is the set of rules governing queue discipline. These include the order in which queued transactions are served; priority arrangements; and, possibly, allowances for "cheating." The two most common arrangements for transaction service are first-in/first-out and first-in/last-out. In addition, priority arrangements can be defined focus on the handling of important transactions as they enter the system; preemptive-priority cases get served directly, usually by displacing a transaction being served, whereas non-preemptive-priority cases are placed at the front of the queue and therefore are accommodated by the next available server.

There exists specialized notation that describes the assumptions of any given queueing theory model called Kendall notation (named after Sir David Kendall). This has the form $A/B/\sigma/k/M/Z$, where A is the distribution of arrivals, B is the service time distribution, σ is the number of servers, k is the total number of transactions that can be either served or stored in the queue, M is the population size from which arrivals are drawn, and Z is a description of the queue discipline.

So, for example, $M/D/3/8/40,000/FIFO$ might describe a barber shop with exponential arrivals, deterministic service (identical cuts), 3 barbers, 5 seats for waiting customers, in a medium-sized town, and serving in order of arrival. It is typical, however, to drop the last three terms in the list when they are obvious from the context of the problem, especially the population size, which cannot be controlled and often does not affect the model specification.

The most straightforward and common model specification is $M/M/\sigma$: exponentially distributed interarrival time (therefore, Poisson distributed arrivals for time period t), exponentially distributed service times, and σ servers. Most texts (cf. Gross & Harris, 1998) start with these systems because, with mild assumptions, many common empirical situations can be described effectively.

QUOTA SAMPLE

Quota sampling is a method of selecting respondents for surveys. Survey administrators assign quotas to interviewers that define groups of respondents by using a few key demographic characteristics. Interviewers fill their quotas by choosing individuals whose characteristics match these characteristics as respondents. When the responses are combined for all of the respondents, the characteristics of the sample precisely match specified demographic characteristics of the survey population. For example, an interviewer may be assigned a quota of four African Americans, eight whites, two Hispanics, and two Asian Americans, half of which live in the central city and half of which live in the suburbs. When all of the interviews are completed, the aggregate statistics for the SAMPLE and the study POPULATION will match exactly for the demographic characteristics that were included as interview criteria. However, matching on aggregate statistics does not ensure that the sample will accurately reflect the population on the variables that are of interest in the study.

The most infamous example of the BIAS that can occur with quota sampling involves polling for the 1948 presidential election. This election pitted Harry Truman, the Democratic candidate who had assumed the presidency when Franklin D. Roosevelt died, against Thomas Dewey, the Republican candidate. Three polling firms—Roper, Gallup, and Crossley—all declared Dewey as the winner based on interviews that had been conducted using quota sampling methods. Of course, Truman won with just under 50% of the popular vote, beating Dewey by nearly five percentage points. The quota samples were carefully matched to census data on age, race, gender, rent paid, and residence, but the interviewers had chosen too many Republicans. Republicans were easier to interview, either more willing to participate or more approachable, and thus Democrats were underrepresented in the interviews. After that election, newspapers were filled with stories about the failure of the pollsters, as well as many commentators. Subsequently, all three polling firms dropped quota sampling techniques.

The failure to accurately predict the 1948 election provided an impetus toward the use of PROBABILITY SAMPLES and very limited use of quota samples for social science research as well as polling. Most pre-election polling relies on RANDOM DIGIT DIALING (RDD) to select households from which adult respondents are selected at random, or random computer-generated selection of a sample from an automated list of eligible voters. Specific individuals are identified by these survey procedures, and interviewers are not allowed to substitute respondents, thereby eliminating interviewer discretion and selection bias.

BIAS AND QUOTA SAMPLING

The principal reason that the quota samples may not provide accurate information about the population is that the interviewers have discretion over who is interviewed. Whenever human judgment is allowed to determine who is selected, even though, in this case, the interviewers must meet demographic quotas, unintentional bias creeps into the selection process. Although the bias is unintentional, it can cause significant errors in the study data and the estimates (e.g., means, proportions, or REGRESSION COEFFICIENTS) that are produced from the data.

Quota samples are NONPROBABILITY SAMPLES, which are sometimes referred to as PURPOSEFUL or CONVENIENCE SAMPLING. Nonprobability samples have the common characteristic that human judgment has a role in determining which individuals are selected to respond to the interviewers' questions. Nonprobability samples are often contrasted with PROBABILITY SAMPLES, where each individual in the study population has a (known), nonzero chance of being selected as a RESPONDENT. Probability samples rely on a random mechanism to identify the individual study population member to respond to the interviewer. Once identified, no substitution is allowed by the interviewers (Hess, 1985). If the identified individual cannot be reached or refuses to respond, the case is considered missing data and contributes to the NONRESPONSE BIAS for the study. With quota sampling, a refusal leads to an interviewer identifying another individual with the necessary characteristics and interviewing the newly identified person to fill his or her quota. Because quota samples do not begin with lists of the study population or maintain records of refusals, it is impossible to analyze the potential bias in these samples. However, many studies and analytical procedures have been conducted

to estimate the bias stemming from nonresponse on surveys using probability samples (Keeter, Miller, Kohut, Groves, & Presser, 2000).

SAMPLING METHODS RELATED TO QUOTA SAMPLING

Although quota samples are relatively rarely used in contemporary social science, there are several types of sampling methods that are similar and are used. One type of probability sampling, proportionate STRATIFIED SAMPLING (Henry, 1990; Kish, 1965), is sometimes confused with quota sampling because both can precisely replicate a few demographic characteristics of the study population. However, proportionate stratified sampling uses a random selection procedure, rather than interviewers, to select respondents. To use proportionate stratified sampling, a list of the study population that contains information about the variables that are used for MATCHING must be obtained. All of the individuals are then placed into mutually exclusive groups, or strata, based on the key variables. The sampling fraction for the study—that is, the percentage of the population that is to be drawn for the sample ($f = n/N$, where f is the SAMPLING FRACTION, n is the sample size, and N is the population size)—is applied to each stratum to determine the sample size for each stratum ($n_s = fN_s$). Finally, a random process is used to select the required number of respondents from each stratum (n_s). This process ensures that the sample selected and the study population will match on the key variables, and interviewer selection is removed as a form of bias.

In order to take advantage of the speed and low cost of quota samples, some survey researchers tried to combine quota sampling and proportionate stratified sampling into a technique that is known as “probability sampling with quotas” (Sudman, 1976). This

technique assigns interviewers to conduct interviews within specific neighborhoods, usually in a specific block, at specific times, and requires them to match a few demographic characteristics of the census tract that contains the specified block. With more controls and recordkeeping on the part of interviewers, biases due to refusals can be estimated and reduced.

Another use of quotas in sampling is to establish limits on the number of interviews from each stratum in a stratified sample. Often, this is done to oversample underrepresented groups, such as racial-ethnic minorities. All respondents are chosen by probability sampling methods, but once the quota for a stratum is reached, interviews with members of that stratum are curtailed after information identifying them as stratum members is obtained.

Quotas are also used in qualitative studies and other studies where an objective is to obtain data from a heterogeneous group of study population members. Although these studies yield biased population estimates, they increase the possibility that contrasting cases will be included in the study, and the differences between these cases can be explored through the research.

R

R

The *R* is the symbol for a MULTIPLE CORRELATION COEFFICIENT. The bivariate correlation coefficient correlates two variables, say, *X* and *Y*. The multiple correlation coefficient is the correlation between two or more INDEPENDENT VARIABLES— say, X_1 , X_2 , and X_3 —and DEPENDENT VARIABLE *Y*. In this example, it would tell us how all three of these independent variables, taken together, correlate linearly with *Y*. The *R* ranges in theoretical value from .00 to 1.00. A high number indicates a high degree of linearity. A low number indicates a low degree of linearity, but does not rule out a high degree of NONLINEARITY. It should be noted that *R* is also used to label a statistical computer program that bears many similarities to S-plus and is gaining popularity in the social sciences.

—Michael S. Lewis-Beck

r

The *r* is the symbol for the PEARSON CORRELATION COEFFICIENT, as estimated in a SAMPLE. It is important to distinguish it from the population value, rho (ρ). It is the leading measure of correlation between two QUANTITATIVE VARIABLES. It assesses the strength of linear relationship, and goes from +1.0 or -1.0 to .00.

—Michael S. Lewis-Beck

RANDOM ASSIGNMENT

Random assignment refers to a way in which subjects are allocated into groups in an EXPERIMENT. One group is typically the CONTROL GROUP, and there can be one or more experimental groups. This way, the systematic effects of all other variables cancel out, and we can better assess the effect of the TREATMENT variable. Random assignment also makes it possible to make use of statistical inference methods and draw conclusions from the population from which the data came.

Many of the main ideas for how to run experiments originated with the British statistician Sir Ronald A. Fisher. He worked extensively with agricultural experiments. With many plots of land available for experiments, the question became how one would allocate various plots to the control and experimental groups and minimize the effect of variables other than the treatment variable. He wanted the assignment to be such that there would be no underlying factors that could explain the outcomes of the experiment. The effects of all variables other than the experimental variable should cancel out. The effects of these variables can never be completely eliminated, but their effects should not have a systematic presence in the data. Whatever effect there would be of all other variables gets absorbed in the residual variable.

Fisher's answer to this problem was to allocate the various elements (plots of land, people, animals, plants, etc.) to the different treatments in a random fashion. A random assignment means allocating elements to treatments such that there are no systematic effects of all variables other than the experimental

variable(s). When there is a control group and only one experimental group, one way to perform the random assignment is to toss a coin for each element. A “tail” would assign an element to the control group and a “head” to the experimental group. After the assignment is finished, there would be about the same number of elements in each of the two groups, and there would be no systematic effect of any other variables on the outcomes of the experiments.

A coin toss is a rather primitive way of assigning elements to treatments. Another way is to use a table of RANDOM NUMBERS. After a random starting point in the table, one can make use of whether a number is an odd or an even number. Many computer software packages generate random numbers that can be used for the random assignment of elements to control and experimental groups.

It is also possible to have a random assignment of elements when there is more than one experimental group. If Fisher planned to compare four different types of grain, plots of land would be assigned to the four experimental groups and a control group in a similar, random fashion.

Random assignments are used for the same purpose as random SAMPLING methods in observational studies. Random assignments and random sampling are needed in order to perform statistical HYPOTHESIS TESTING and the construction of CONFIDENCE INTERVALS.

RANDOM DIGIT DIALING

Random digit dialing is a sampling technique used in TELEPHONE SURVEYS. Instead of using telephone directories that may be incomplete or out of date, random numbers are used to constitute telephone numbers. The digits relating to the target areas are

not randomly arrived at but are simply tacked onto the beginning of the randomly generated numbers. In the United States, this generally means adding a randomly generated four-digit code to the three-digit local exchange.

—Alan Bryman

RANDOM ERROR

Randomness lies at the heart of STATISTICAL INFERENCE. It is based on the notion that if an observation or a measurement is repeated, then most of the time, a different value is observed.

Randomness exists when it is not possible to predict the outcome of the next observation, either in a SURVEY or an EXPERIMENT. It follows that, in the presence of randomness for a variable, there will be RANDOM VARIATIONS in the observations, and the variable becomes a random variable. The magnitude of such randomness is measured by the random error.

The variation in the observations of a random variable leads to variations in any SAMPLE statistic computed from the data. Thus, a sample MEAN will vary from sample to sample, just as the percentage of voters who support a candidate varies from one sample of voters to another.

The variation in a sample statistic from one sample to the next can be seen when multiple samples are taken. A particular polling organization may not do repeated sampling, but prior to any major election, several polling organizations do their own studies, and the percentages they report vary from one study to the next. One of the reasons they vary is because of the randomness inherent in any sampling procedure. It is also possible to simulate such variation with the proper statistical software. Simulating samples of size $n = 1,000$ and a probability of 0.5 of drawing a 1 or a 0, these are the first few sample percentages of draws that are 1: 50.4, 50.4, 48.4, 51.4.

Such variation is known as the random error associated with the percentage. It is unfortunate that the word ERROR is associated with this variation, because there is nothing “wrong” with such variation. But to the extent that there exists one true percentage value in the population, any deviation of a sample percentage from this true POPULATION parameter can be thought of as an error.

HISTORICAL ACCOUNT

Physicists have long been concerned with how to measure characteristics of physical objects. Even repeated measures of the length of a yardstick result in different measurements, even though we realize that the yardstick has only one, fixed length (given fixed temperature, etc.). Physicists finally accepted this variation, and they attached the name “error” to the difference between an observed value and the true, underlying value. Statisticians carried on with the term when they observed different values of a statistic from different samples, even though this variation is due to sampling effects.

APPLICATIONS

The existence of the random error leads to the question of what the magnitude is of this error. If the magnitude of the random error is known, then it is possible to state whether a particular sample statistic exceeds the random error or not. How much would we expect a sample percentage to vary around the true parameter value? Statisticians have developed formulas for the computation of magnitudes of the random error. If such formulas do not exist, it is often possible to simulate many repeated samples with the proper software and thereby compute the magnitude of the random error.

EXAMPLES

One way to measure the magnitude of the random error is to find the STANDARD DEVIATION of a sample statistic across many different samples. Such a standard deviation is mostly known as the STANDARD ERROR of a sample statistic, to distinguish it from the standard deviation we compute from a set of single observations. For a sample of size 1,000 from a population split 50/50, the standard error of the sample percentage becomes 1.6. In most cases, two times the standard deviation, or two times the standard error, will include most of the data. Twice 1.6 equals 3.2, and most of the sample percentages from various samples should fall in the range from $50 - 3.2 = 46.8$ to $50 + 3.2 = 53.2$.

However, we are interested most often in whether a particular sample statistic lies within the random error inherent in the sampling procedure, or whether the sample statistic lies further away from the

presumed value of the population parameter. Suppose we hypothesize that a population percentage equals 50%. From a sample of 1,000 observations, the observed sample percentage equals 56.7%. Does 56.7% lie within the range around 50% produced by the random error, or is 56.7% beyond the random error produced by the sampling procedure?

We can now conclude that the sample percentage lies beyond the error that can be expected by the sampling error. We could change the sample percentage to a value of the standard normal variable. With a value larger than 1.96, we conclude that the deviation of the sample statistic from the hypothesized population parameter exceeds what can be expected on the basis of the random error itself. Here, $z = (56.7 - 50.0)/1.58 = 4.24$. For less than once in 10,000 different samples would we observe such a large value or a larger value of the standard normal variable. From this, we conclude that the hypothesized value of 50% for the population in its support of the candidate must be wrong. For the observed sample value to lie within the random error of the population percentage, the population percentage must lie closer to the observed sample value of 56.7%.

Any sample statistic will have its associated random error, as expressed in its standard error. We have some control of the magnitudes of the random errors from the way the sample is collected and which variables are used in a particular study. One way to make the random error smaller is to have a larger sample. The number of observations in the sample often figures directly into the computation of the standard error of a sample statistic. One drawback is that the sample size often enters the formulas through its square root, and it takes much larger sample sizes to get the desired effect. Because of the square root, we need a sample four times as large to get half the standard error. In MULTIPLE REGRESSIONS, COLLINEARITY will increase the standard error of the regression coefficients.

RANDOM FACTOR

Factor is another word for *variable*. Factor is commonly used in the running and analysis of data from EXPERIMENTS. For experiments, the word *treatment* is also used instead of factor or variable. For observational data, TREATMENT is often not an appropriate term. In a study of religious affiliation, treatment would not be a good term for a nominal variable with categories Catholic, Jewish, Protestant, other. It is not as if people are treated with different religions the way a plot of land is treated by a fertilizer.

However, for an experimental study of the effect of a NOMINAL VARIABLE on a QUANTITATIVE VARIABLE, the term *treatment* and the term *factor* are interchangeable, and both terms are used. Such a study would call for ANALYSIS OF VARIANCE, and because of its historical connection with experiments, *treatment* or *factor* are both used instead of the more neutral term *variable*. For such a study, the INDEPENDENT VARIABLE (treatment, factor) is thought of as having different *levels* instead of simply different *values*.

A factor in analysis of variance can be one of two kinds: *fixed* or *random*. A factor is considered fixed if we make use of all the possible categories of the factor. Gender, for example, would be a fixed factor when we use female and male as the two categories. For most purposes, there are no other categories for this variable. On the other hand, a factor is random if we have data for only some of the categories. In a study of differences among the 50 states, we can first choose a random sample of states, say, 10, and then collect data on the DEPENDENT VARIABLE from a sample from each of those chosen states.

Random factors are typically variables with such a large number of categories that it is not feasible or economical to collect data on the dependent variable for each of the categories. By first taking a random sample of categories and limiting the study to those categories, the study becomes more manageable.

An analysis of variance using a fixed factor as the independent variable is denoted as a MODEL I ANOVA. Similarly, an analysis using a random factor is denoted as a MODEL II ANOVA. In the case of only one factor, the computations of sums of squares and *F* VALUES are identical for the two types of models. But for two or more factors, it makes a difference in the computations whether we use a Model I or Model II. For example, in a two-way analysis of variance, in a Model I analysis, we

divide the row, column, and interaction mean squares by the residual mean square to get *P* VALUES. But in a Model II analysis, we divide the row and column mean squares by the interaction mean square to get *p* values.

It is also possible to have a mix of factors, some fixed and some random. Because it typically makes a difference whether a factor is classified as fixed or random, it is important to make certain one has computer software that takes this difference into account.

RANDOM NUMBER GENERATOR

A random number generator is any process that generates a sequence of values that is in some sense unpredictable. Random number generators are widely used in SIMULATION, Monte Carlo statistical techniques, and cryptography. True random numbers are generated by a natural process such as radioactive decay or atmospheric noise. However, most applications use pseudo-random numbers, which are generated by a deterministic equation that produces a sequence of values that has statistical properties similar to those of a true random sequence. Pseudo-random number generators are incorporated into most computer languages and in numerical software such as spreadsheets and statistical packages.

The most common technique for generating pseudo-random number generators is the linear congruent generator

$$y_{n+1} = (ay_n + b) \bmod m.$$

For example, in the ANSI C computer language, the `rand()` random number function has $m = 2^{31}$; $a = 1103515245$, and $b = 12345$. For reasons of computational efficiency, m is usually a power of 2; a and b are chosen experimentally on the basis of

the characteristics of the sequences produced by the equation. The linear congruent function generates integers in the range $[0, m - 1]$; if y_n is divided by $m - 1$, a sequence of uniformly distributed random numbers in the interval $[0, 1]$ can be generated. Uniform random numbers can, in turn, be used to generate random numbers for other PROBABILITY distributions, such as the normal distribution, by using specialized ALGORITHMS or by inverting the appropriate cumulative probability distribution function.

Because the linear congruent generator uses only y_n to determine y_{n+1} , once a value occurs more than once, all subsequent values in the sequence will be repeated in the same sequence that was generated after the first occurrence of that value. The number of values that can be generated without repetition is called the “cycle” or “period” of the generator. This is necessarily less than m , and in a poorly constructed generator, the period may be quite short.

An alternative approach is called the lagged Fibonacci generator, which has the form

$$y_{n+1} = (y_{n-i} + y_{n-j}) \bmod m$$

for some positive integers i and j . Fibonacci generators can have considerably longer periods, on the order of 10^{200} to 10^{500} .

The initial value used in a linear generator is called the “seed.” Different sequences will be generated depending on this value. In some applications, the same seed is used repeatedly so that the same sequence is generated each time; in other applications, the seed is set randomly, often using some randomly varying physical process, such as the number of seconds since the computer was turned on.

Developing high-quality pseudo-random number generators has proven to be a remarkably difficult problem in computer science; Knuth (1997) remains the definitive work on the problem. Generators can be assessed using a number of statistical tests; the key characteristics of a high-quality generator are a long period, absence of serial correlation between y_n and y_{n-k} , and uniformly filling of the interval $[0, m - 1]$. Finally, because applications often require the generation of billions of pseudo-random numbers, computational efficiency is important.

True random numbers are used in some specialized applications such as cryptography, where any pattern in the sequence might weaken the system. A number of Web sites exist that provide true random sequences based on physical processes such as

monitoring radioactive decay with a Geiger counter; see <http://www.random.org>. The decimal digits in irrational numbers such as pi or the square root of 2 also form true random sequences; the Web site http://antwpr.gsfc.nasa.gov/htmltest/rjn_dig.html provides sequences of several million digits from various irrational numbers. Unlike pseudo-random numbers, true random number sequences never cycle.

RANDOM NUMBER TABLE

We have all observed one or more numbers being drawn out of a hat in order to determine winners of prizes. For example, admission ticket stubs may be placed in a bowl and shaken before drawing a stub at random and reading off the prize-winning number. This is the function provided by a random number table. Table 1 is a brief excerpt of two lines from a page in a random number table. (The spaces between each set of five digits are present only for ease in reading and should be ignored in reading random numbers across or down the page.)

The entries in a random number table satisfy two basic properties:

1. Every digit from 0 to 9 has the same probability of occurrence (equally likely to occur).
2. The probability of any given number is not affected by the numbers that precede or follow it (independence).

One of the primary uses of a table of random numbers is for selecting a random sample for statistical analysis. Suppose we have a POPULATION of N items, and we wish to select a simple RANDOM SAMPLING of n items. We first assign a number label to each of the N items in the population, using the integers $0, 1, \dots, N - 1$. Those population items whose numbers are read from the random number table will become the elements in the sample. The first step is to choose a random starting point in the table. You could, for example, close your eyes and open the book

Table 1 Excerpt From a Random Number Table

77921	06907	11008	42751	27756	53498	18602	70659	90655	15053	21916	81825	44394	42880
99562	72905	56420	69994	98872	31016	71194	18738	44013	48840	63213	21069	10634	12952

to a random page and then point your finger to a starting point. From then on, we read successive digits across the page left to right (or right to left, or down the column, or diagonally, etc.). If $N - 1$ has x digits, we read x digits at a time in succession, ignoring any blank spaces.

For example, suppose we have a population of 683 items, and the above excerpt shows our random starting point, at the upper left-hand corner. Then, reading left to right, the numbers of the items to be included in the sample are 779, 210, 690, 711, 008, 427, 512, 775, 653, 498, and so on. Here, we have to throw out all numbers greater than 683. We keep reading successive three-digit numbers until we have obtained n items. The sample can be selected with replacement (if population item number 328 comes up more than once in the list of random numbers, that item is included in the sample more than once), or without replacement (if item 328 comes up more than once, it is thrown out after the first time).

It is important that every effort be made to ensure that the starting point in the table is different each time the table is used. One may wish to use the random number table itself to select the starting point. For example, we might read 56 from the excerpt above to indicate that we should begin on page 5 with the sixth digit.

The first random number table was produced in 1947. The RAND Corporation published the book titled *A Million Random Digits* in 1995; this book is still available for purchase and also appears online at <http://www.rand.org/publications/classics/randomdigits>. A paperback version was published in 2002.

—Jean D. Gibbons

RANDOM SAMPLING

Random sampling refers to SURVEY sampling designs that meet the criteria necessary to permit the use of randomization-based methods of STATISTICAL INFERENCE. The term *probability sampling* is synonymous. The defining characteristics of a random sampling design are the following:

1. The study population is fully defined.
2. The design is specified.
3. The design is objective.
4. The design is replicable.
5. Every unit in the population has a known probability of being selected.
6. All selection probabilities are nonzero.

These criteria warrant a little further explanation. The first seems straightforward but is often overlooked. It is necessary to define precisely the units of interest to the survey and the boundaries of the population. For example, it is not sufficient to say “all adults.” The definition should encompass geography, time, civil status, age range, and other relevant factors. A better definition might be “All people aged 18 or over whose sole or main residence as of 10 July 2003 was a private household in one of the 48 mainland states of the USA.” If the survey is carried out over a long period of time, we should also specify how we deal with the distinction between stock and flow.

Specification (Criterion 2) necessitates a clear and full description of the process that resulted in the selection of the sample.

Objectivity requires that each selection—and each stage in the selection process, because many designs are multistage—is governed by a random chance mechanism. It is not permissible for any subjective judgment to influence the selection of sample units. This is perhaps the heart of the definition of random sampling. A number of studies have shown that both experts and nonexperts produce samples that are seriously in error in terms of important characteristics if asked purposively to select a sample that they believe to be representative. Teachers of sampling also observe this phenomenon regularly in class exercises. Selection by means of a chance mechanism is the only way to avoid SYSTEMATIC ERROR (while also being able to measure variable error).

REPLICABILITY requires that another researcher, given identical circumstances, would be able to implement exactly the same design. This does not mean that he or she would necessarily replicate the *selected sample* (in fact, this would be extremely unlikely), but that he or she could replicate the *design*, that is,

reproduce the stages in the process and reapply the random mechanisms where appropriate.

Criterion 5 states that it is necessary to know the selection probability of every unit in the population. In fact, for purposes of estimation, it is necessary to know the probabilities of only those units that were actually selected—not of the ones that were not selected. The point is that it must, in principle, be possible to calculate the selection probability of any unit in the population. To meet this requirement, it is necessary first to have a design that is specified and objective, and, additionally, to have collected and recorded necessary information during the course of sample selection. For example, if the design involves selecting residential addresses from a list and subsequently selecting one person at random to interview at each address, it is necessary to record the number of eligible people at each sample address.

The final criterion is that every unit in the population must have a chance of being selected. It is not permissible for any units to be completely excluded from the selection process. If this happened, and the excluded units were in any way systematically different from the included units, a “coverage bias” would result.

Random sampling is widely considered to be the only acceptable approach for public sector and academic quantitative surveys from which descriptive statistics are to be produced. In the absence of other sources of systematic error (such as NONRESPONSE BIAS and measurement bias), it provides the basis for UNBIASED estimation. However, model-based approaches to INFERENCE argue that randomization is not necessary provided that sources of systematic error in the sample structure are recognized in the model (e.g., as covariates). Increasingly, the two approaches are combined by the use of model-assisted inference based on random sampling (Brewer, 2002).

Many government and academic social surveys have a requirement for random sampling. This is set out in protocols such as those for the European Labour Force Surveys (Eurostat, 1998), European Social Survey (ESS-CCT, 2001), and International Social Survey Programme (Park & Jowell, 1997). However, it is not uncommon to find surveys that purport to use random sampling but, in fact, diverge from the criteria in important ways—perhaps by allowing PURPOSIVE selection of sample areas at the first stage, or by using QUOTA SAMPLING within households or other randomly selected units.

A wide range of sampling designs is possible within the definition of random sampling, including the use of MULTISTAGE SAMPLING, proportionate or disproportionate STRATIFIED SAMPLING, CLUSTER SAMPLING, and SYSTEMATIC SAMPLING.

With random sampling, it is necessary to make considerable efforts to maximize survey response rates. Without this, SAMPLING BIAS may simply get replaced by nonresponse bias. This is sometimes seen as a disadvantage of random sampling, because the cost per survey response is typically much higher than with nonrandom methods (particularly in the case of face-to-face interviewing). The alternative to random sampling methods is purposive sampling methods, of which quota sampling methods are the most well known.

RANDOM VARIABLE

In statistics, a variable can be *fixed* or *random*. A random variable is a variable where we cannot predict the value for an observation or necessarily get the same value when we repeat the observation. A fixed variable does not change value across repeated measurements. The distinction between the two types can be rather fluid, but it is usually clear from the context whether a variable is fixed or random. Statistical inference (HYPOTHESIS TESTING and CONFIDENCE INTERVAL estimation) applies only to random variables.

We would think that the measure of the length of a yardstick is a fixed variable, because the length does not change. But physicists established early on that when such a stick is measured many times, the results were

not the same from measurement to measurement, even though the stick stayed the same. Thus, the length is a random variable, and the difference between the actual length, whatever it is, and the observed length is due to MEASUREMENT error.

In the study of relationships between variables, the INDEPENDENT VARIABLE(S) is often considered a fixed variable, whereas the DEPENDENT VARIABLE is considered a random variable. In a study of the relationship between education (measured as number of completed years in school) and income, education would be considered a fixed variable and income would be considered a random variable. The education of a person would be the same no matter how often it is measured; people with 16 years of education would continue to have that value (unless they go on to graduate school). People with the same education would have different incomes, and there would be a spread of income values around a mean income for each particular educational group.

In a REGRESSION analysis, usually there are variations in the dependent, random variable around the regression line for each value of the independent, fixed variable. This is the reason we minimize the vertical SUM OF SQUARES of the dependent variable around the regression line, instead of minimizing the sum of squares in the horizontal or perpendicular direction in the scatterplot. Minimizing the sum of squares of the dependent variable enables us to bring the machinery of regression analysis to these DATA to find results such as the regression line, the CORRELATION coefficient, and *P* VALUES. All of the formulas for ordinary regression analysis in popular statistical packages are based on the independent variable(s) being a fixed variable(s) and the dependent variable being a random variable.

What happens when both the independent and the dependent variables in a regression analysis are considered random variables? There are times when it makes sense to consider both independent and dependent variables as random variables. In this situation, the mathematical derivations of the necessary formulas become much more difficult and do not lead to the same simple formulas as with a fixed, independent variable and random, dependent variable. Mostly, however, people overlook the problem and use the formulas for ordinary regression anyway, presumably without too much damage to the analysis and the result.

RANDOM VARIATION

The study of variation is a central idea in statistics. Variation means that when we measure something over again, we get a different result, and we cannot predict the outcome of any future observation. Any time we have a RANDOM VARIABLE, there is, by definition, variation attached to the variable.

Two questions arise: (a) How do we measure variation? and (b) How much of the variation in a variable is produced by other variables? A simple way to measure the amount of variation is to compute the standard deviation or some related STATISTIC. The contribution to the variation by other variables is usually measured by sums of squares or MULTIPLE CORRELATIONS.

One way to understand the magnitude of variation in a variable is to take the variable as a DEPENDENT VARIABLE and introduce one or more INDEPENDENT VARIABLES, say, in a REGRESSION analysis. Such an analysis results in various sums of squares. The total sum of squares, the numerator in the VARIANCE of the dependent variable, gives a measure of the total variation in the dependent variable. There are two reasons why the values of the dependent variable are different. One is that units have different values of the independent variables; the other reason is that there are effects of variables other than the independent variables. The combined effects of all these other variables are known as the effect of the RESIDUAL variable (or ERROR variable).

Some of the total variation can be traced to the independent variables. We can use the estimated regression equation to compute a set of predicted values of the dependent variable. Why are these predicted values different from each other? They are different because they were computed from the independent variables, and observations have different values on the independent variables. Thus, the variation in the predicted values of the dependent variable is due to the independent variables. The amount of this variation is measured

by computing the REGRESSION SUM OF SQUARES. It gives the effects of the independent variables on the dependent variable in terms of how much variation in the dependent variable is produced by the independent variables.

The difference Total Sum of Squares minus Regression Sum of Squares gives the magnitude of the effects of the residual variable, or the amount of the total variation produced by all other variables. This difference is known as the RESIDUAL SUM OF SQUARES or the error sum of squares (even though there is nothing wrong with it). This sum of squares can also be found from taking the difference between observed and predicted values of the dependent variable and adding the squares of these differences.

Each time we add another variable with its parameter to the model, the residual sum of squares stays the same or gets smaller. But with more parameters, the model becomes less parsimonious. In the extreme, by including as many parameters as there are observations, the residual sum of squares equals zero. However, nothing has been gained, because we have only replaced n quantities (data points) by n other quantities (parameters).

RANDOM WALK

A random walk is a STOCHASTIC process sometimes used as a model for TIME-SERIES data. Perhaps the best known application of a random walk is to stock market prices on successive days.

Suppose that $[u_t]$ is a sequence of RANDOM VARIABLES that is mutually independent and identically distributed. As such, $[u_t]$ has a constant mean μ and variance σ^2 . The covariance between u_t and u_{t+k} , $k = \pm 1, \pm 2, \dots$, is equal to 0. A process that would produce random variables with these properties is sometimes called a “purely random process” or WHITE NOISE.

Drawing heavily on Chatfield’s (1996) fine exposition, a set of random variables $[y_t]$ is viewed as a random walk if

$$y_t = y_{t-1} + u_t. \quad (1)$$

In practice, the time series is assumed to start at 0 when $t = 0$. Then, $y_1 = u_1$ and $y_t = \sum_{i=1}^t u_i$.

It follows that $E(y_t) = t\mu$ and $\text{Var}(y_t) = t\sigma^2$. Because the mean and the variance change with t , a random walk is not stationary. However, taking the first difference, one gets $(y_t - y_{t-1}) = u_t$, the purely random process with which we started.

A random walk is a special case of a first-order AUTOREGRESSIVE process,

$$y_t = \alpha y_{t-1} + u_t, \quad (2)$$

where $\alpha = 1$. The links between a random walk and Autoregressive Integrated Moving Average (ARIMA) models more generally are discussed in Box, Jenkins, and Reinsel (1994).

RANDOM-COEFFICIENT MODEL.

See MIXED-EFFECTS MODEL;
MULTILEVEL ANALYSIS

RANDOM-EFFECTS MODEL

ANALYSIS OF VARIANCE (ANOVA) models can be used to study how a dependent variable Y depends on one or several factors. A factor here is defined as a categorical independent variable; in other words, an explanatory variable with a nominal LEVEL OF MEASUREMENT. In a random-effects ANOVA model (also called a Type II ANOVA model), the effects of the categories of each factor are modeled as random variables; one could say that this is a model with random parameters. More specifically, when a given factor has

values $1, 2, \dots, K$ in the data set, and for case i , the value of this factor is indicated by $k(i)$, then a random effect of this factor for case i is defined by the term $U_{k(i)}$ in the linear model for Y_i , where it is assumed that $U_1, \dots, U_K$ are independent and identically distributed RANDOM VARIABLES. Usually, a normal distribution is assumed for these random variables. Such a model is appropriate if the categories of this factor are regarded as a random sample from some population and if the statistical inference aims at drawing conclusions that hold for this population. This contrasts with FIXED EFFECTS MODELS, which are described in another entry. Random-effects ANOVA models also are called VARIANCE COMPONENTS MODELS.

Two examples of studies where random-effects models can be appropriate are (a) educational studies about educational achievement of pupils where teachers are an important factor, and the researcher is primarily interested in drawing conclusions that apply to the population of teachers rather than specifically to the teachers included in the present study; and (b) studies in the framework of GENERALIZABILITY THEORY and INTERRATER RELIABILITY, where ratings on individuals are obtained from each of several observers, and one of the interests is in the contribution of the observers (drawn randomly from some population of observers) to the variability of the measurement obtained by averaging the ratings of one individual over the observers.

Random effects occur similarly in extensions to other, more complicated models, such as GENERALIZED LINEAR MODELS or nonlinear regression models. Their definition, then, is the same: The effects of the categories of each factor are modeled as random variables.

The term *random-effect models* is reserved for models in which each factor has random effects. Models containing some random as well as some fixed effects are called MIXED-EFFECT MODELS, and these are used more frequently than pure random effect models. The random effects as defined above can be regarded as random main effects of the levels of a given factor. A generalization is a random coefficient of a numerical explanatory variable (see RANDOM-COEFFICIENT MODELS). For hierarchically nested factors, models including random coefficients as well as fixed effects are also called HIERARCHICAL LINEAR MODELS. These models are the basis of most procedures of MULTILEVEL ANALYSIS.

RANDOMIZED-BLOCKS DESIGN

As the outcome of an EXPERIMENT, the values of the DEPENDENT (response) VARIABLE will differ from each other from one experimental unit to the next. It is this variation in the values that gives us clues about the effects of the INDEPENDENT (treatment) VARIABLES and perhaps other variables. The variation in the values of the response variable is typically measured by subtracting the mean from each observation, squaring all the differences, and adding all the squares. This procedure gives the total sum of squares, $TSS = \sum (y - \bar{y})^2$.

Experiments can be set up in different ways, using different designs. The goal of any design is to isolate the effects of the TREATMENT variables from other variables. We want the variation in the values of the response variable to be due to the treatment variables and not to other, extraneous variables. In a randomized-blocks design, similar units are gathered in groups called blocks. Both experimental and CONTROL GROUPS contain blocks.

EXPLANATION AND EXAMPLE

For example, a psychologist may have a suspicion that the gender variable affects the outcome of an experiment in perception. Without the use of blocks, the experiment consists of an experimental and a control group. After the experiment, there is a mean score for the experimental group and a mean score for the control group. The impact of the treatment can then be seen in how different these two means are from each other and from the overall mean. One way to measure this impact is to compute the treatment sum of squares.

The difference between the total sum of squares and the treatment sum of squares becomes the residual sum of squares. This sum gives the combined effects of all variables other than the treatment variable, including

gender. To establish STATISTICAL SIGNIFICANCE, it is common to divide the treatment and the residual sums of squares by their appropriate degrees of freedom to get the mean squares. They are used to find the value of the statistical F variable, where F = treatment mean square/residual mean square. The larger the F , the smaller the P VALUE and the more significant the results are.

One way to get a large value of F is to have a large numerator, and another way is to have a small denominator. There is not much that can be done with the numerator, but it may be possible to reduce the denominator. Part of the reason the values of the dependent variable are different may be because people are of different genders. If it were possible, somehow, to take out the magnitude of this source of variation in the residual sum of squares, then we would get a smaller, new residual sum of squares and thereby a smaller denominator for F , which again would give a larger value of F .

Here is where the idea of blocking comes in. By identifying the gender of each subject, it is possible to arrange the mean perception scores for each gender and for treatment/control groups in a table (see Table 1).

Table 1 Mean Scores for Blocks and Treatments

Block	Treatment Group	Control Group	Mean
Female	$\bar{y}_{ft}$	$\bar{y}_{fc}$	$\bar{y}_f$
Male	$\bar{y}_{mt}$	$\bar{y}_{mc}$	$\bar{y}_m$
Mean	$\bar{y}_t$	$\bar{y}_c$	$\bar{y}$

Such an arrangement of the means does not change the computation of the treatment sum of squares. It still simply involves the means for the treatment and control groups. Thus, the numerator for the F does not change from how it was computed without blocking.

But it is now possible to compute a block sum of squares. It is found from the means of the two gender groups, the number of observations in each block, and the overall mean. This sum of squares very much resembles the treatment sum of squares above. It is found with the following formula: Block Sum of Squares = $\sum n_f = (\bar{y}_f - \bar{y})^2 + \sum n_m (\bar{y}_m - \bar{y})^2$. Next, we subtract this sum of squares from the old residual sum of squares to get a new residual sum of squares, smaller than the old one. By properly adjusting for the various DEGREES OF FREEDOM, we get a new and smaller denominator for F than what we had without blocking. That results in a larger F and a smaller p value.

The key here is that we have been able to “purify” the residual sum of squares. The residual variable can be seen as the net effect of all other variables, the blocking variable is one of them, and we have been able to take out the effect of this one variable. Therefore, the remaining variation in the residuals is, most of the time, smaller than it was. The residuals are now found as the difference between each observation and the appropriate doubled subscripted mean above; this is instead of the difference between an observation and the mean of either the treatment or the control group, when blocks were not taken into account.

HISTORICAL ACCOUNT

Much of the thinking behind the planning of experiments goes back to the pioneering ideas by Sir Ronald A. Fisher on his work on agricultural data. He noted that on a field of land divided up into experimental units, units in one part of the field may be different from units in other parts of the field because of things such as difference in altitude and difference in amount of sunlight. If these factors were not in some way taken into account, they could well influence the amount of yield from the different units and affect the variation in the values of the yield. One way around such a problem is through the use of a randomized-blocks design. Instead of simply dividing the units into experimental and control groups, first it would make sense to group similar land units into what he called blocks.

APPLICATIONS

Without blocking, the analysis consisted of a simple, one-way analysis of variance. With blocking and the mean arranged as in the table above, the analysis consists of a two-way analysis of variance but without taking into account any idea of a treatment-block interaction effect.

RANDOMIZED CONTROL TRIAL

A randomized control trial (RCT) is a type of evaluation research design. RCTs address questions about whether, and to what extent, interventions might “work.” A trial is a test, the term *controlled* indicates the inclusion in the study design of one or more comparison groups, and RANDOMIZED refers to a method of using random allocation to generate intervention and comparison groups. The use of random allocation is the only characteristic that distinguishes RCTs from other prospective evaluation designs. The RCT’s role is to reduce the chances of being misled about intervention impact because of unmeasured factors associated with other ways of selecting intervention and comparison groups. Randomization also permits legitimate statistical statements about the probability that study results are a matter of chance.

WHY RCTs ARE USEFUL

Assessing the effectiveness of different types of interventions is a major challenge for researchers, scientists, policymakers, and the public generally. Does intensive social work input for children with behavior problems actually help these children and their families? What is the impact on children’s literacy of computer-assisted learning? Does introducing criminals to their victims secure lower reoffense rates? Do screening programs for breast or prostate cancer work in reducing deaths from these diseases? Answering such questions requires the use of a research design that permits the impact of the intervention in question to be disentangled, so far as is possible, from other influences, including the social characteristics of the intervention recipients and whatever else is going on in the social context at the time. RCTs can provide rigorous evidence to inform policy and practice decisions about the relative effectiveness of different interventions. As in any research, a good design is only optimally useful if it addresses an important question and is well operationalized.

THE HISTORY OF RCTs

Efforts to control biases in assessing the effects of interventions go back at least three centuries, include both medical and social science, and are based on the important recognition that even well-intentioned

interventions may do harm. Physicians from the 17th century on recommended casting lots to determine which patients would receive a particular treatment. This recognition of the need to compare like with like gathered momentum during the 18th century, such as naval surgeon James Lind’s famous study of scurvy, in which patients with the same condition were assigned to different treatments, and those who got oranges and limes recovered most quickly. The use of alternate or “random” allocation to generate comparison groups became more common after about 1920, with the first detailed descriptions of random allocation processes occurring in the 1930s. The term *control* was used in experimental psychology from the 1870s on to mean a standard of comparison used to check inferences made from an experiment; it comes from “counter-roll,” a duplicate register made to verify an official account.

Although today, RCTs are mainly associated with health care, social scientists have been equally concerned with designing intervention evaluation so as to be able to answer impact questions reliably. In the 1920s, 1930s, and 1940s, researchers, particularly in North America, in education, social welfare, and public policy made extensive use of experimental research designs, and “experimental sociology” was an important field of study. This was followed by “the golden age of evaluation,” from the 1960s to the 1980s, when American evaluators, often with government backing, used RCTs to evaluate a wide range of public policy initiatives, including income maintenance and housing allowance schemes, programs of support for disadvantaged workers, and interventions for former prison inmates.

RCTs AND OTHER RESEARCH DESIGNS TO ASSESS EFFECTIVENESS

An RCT tests the effects of an intervention by comparing defined outcomes in one population that is offered an intervention with those in another population that is not offered it. Potential recipients of an intervention are assigned to intervention or control groups using some method of random allocation (chance), such as tossing a coin or using a computer randomization program. Either individuals or groups (such as schools, hospitals, or communities) can be randomized (“cluster” randomized trials). Cluster RCTs may be particularly useful in the social sciences.

Empirically, results of RCTs usually differ from those of nonrandomized or uncontrolled studies (for

example, the common design of pre- and posttest on one group only). RCTs often yield lower estimates of effectiveness than other types of studies. There are many examples in social science and policy where the results of RCTs have been different from those of observational studies. For example, an RCT of day care for young children, the Perry Preschool Project, has shown with a follow-up of 27 years that this intervention can have long-term beneficial effects on such measures as educational achievement, unintended pregnancy, and criminal behavior, and this is in contrast to the findings of observational studies, many of which suggest deleterious effects of day care.

CURRENT DEBATES ABOUT RCTs

Most recent work on the methodology of RCTs has been carried out in health care by researchers allied with the Cochrane Collaboration (named after Archie Cochrane, an epidemiologist who argued strongly for the synthesis of research evidence based on RCTs). A sibling network, the Campbell Collaboration, was set up in 2000 to apply the same principles to the analysis of evidence about social interventions. This is named after Donald Campbell, a methodologist, whose 1966 book with Julian Stanley, *Experimental and Quasi-Experimental Designs for Research*, established the principles and procedures for the use of RCTs in social science.

Unfortunately, the association of the term “RCT” with medicine leads many social scientists to dismiss this method. Objections to the ethics of RCTs ignore the unethical nature of research designs that cannot properly answer the research question. They also fail to acknowledge the normal practice of uncontrolled experimentation, which ensures that people may be subjected to professional and other interventions with unknown, and possibly harmful, effects. The many thousands of RCTs conducted of social interventions show that this method is practical, even in complex social settings. A well-conducted RCT is a powerful method for assessing strategies for solving some of today’s most pressing social problems.

RANDOMIZED RESPONSE

When asked sensitive or threatening questions within a SURVEY context, respondents frequently lie, despite assurances of confidentiality. Indeed, advancing the cause of social science research is not, for most people, a sufficiently compelling reason to disclose embarrassing or even incriminating information.

Randomized response is a data collection strategy that incorporates lying of a sort into the survey instrument in order to protect respondents. That is, respondents are encouraged to give ambiguous answers based on some random process. Like the popular game show *Jeopardy*, the interviewer knows the respondent’s answer, but not exactly the question to which it is associated.

In its simplest form (Warner, 1965), a respondent is instructed to answer a sensitive question or its converse depending on the outcome of some randomizing device, such as the roll of a die. For example,

- | | |
|-------------------|--|
| Roll 1 or 2: | Have you used drugs in the past month? |
| Roll 3 through 6: | Have you abstained from using drugs in the past month? |

The catch is that only the respondent knows the roll of the die, so both a “yes” response and a “no” response may be either an admission or a denial of drug use, only the respondent knows for sure. Yet, in the aggregate, the prevalence of drug use can be estimated from the SAMPLE percentage of affirmative responses (some of which indicate drug use and the remainder claim abstinence).

The proportion of affirmative responses (π) is

$$\lambda = p\pi + (1 - p)(1 - \pi),$$

where p is the BINARY probability for the randomizing device (e.g., $p = 1/3$ for a 1 or 2 on a die) and λ is the desired prevalence parameter (e.g., the

percentage using drugs in the past month). We can then derive an estimate of the prevalence of the sensitive attribute under investigation from the sample proportion of affirmative responses,

$$\hat{\pi} = \frac{\hat{\lambda} + p - 1}{2p - 1}.$$

Although elegant in its simplicity, pairing a sensitive question with its converse may provoke respondent suspicion about statistical trickery. A more useful strategy, known as the unrelated question approach (see Horvitz, Shah, & Simmons, 1967), enhances respondent comfort by including a nonthreatening alternative. A respondent is instructed to answer a sensitive question or the alternative item depending on the outcome of the randomized device (say, a coin). For example,

Heads: Have you used drugs in the past month?
Tails: Is the final digit of your social security number odd?

In the aggregate, knowing that half the respondents would have been directed to answer the social security number question, and half of those would have responded "yes," we can filter the response distribution accordingly. In estimating the prevalence of drug use, we purge the observed response distribution of the expected number of affirmative responses to the nonsensitive question.

In the years since Warner's seminal paper, numerous alternative approaches using multiple questions, multiple groups, and various randomizing devices have been proposed (see Fox & Tracy, 1986, and Chadhuri & Mukerjee, 1987, for extensive discussions). The objective, of course, is to design a survey question that inoculates respondents in sensitive areas, that is credible, yet that is statistically efficient. The ambiguity created by the randomizing device and the use of multiple questions, designed to reduce evasive response bias, comes at a statistical cost in terms of precision.

The randomized response approach has also been extended to quantitative responses. For example, a respondent may be asked to respond to one of two questions based on drawing a colored ball from an urn:

Blue ball: How many days in the past week have you used drugs?
Red ball: What is the final digit of your social security number?

The mean of the observed responses (Z) is a weighted average of the mean frequency of the sensitive question (X) and the mean of the alternative question (Y), weighted by the probability (p) associated with the randomizing device. Thus, the estimated mean for the sensitive question (X) can easily be derived from

$$\hat{\mu}_X = \frac{\bar{Z} - (1 - p)\mu_Y}{p}.$$

The mean as well as percentage distribution of the sensitive question can be easily derived from the complete collection of responses, based on knowledge of the distribution of the nonsensitive characteristic and the randomizing device.

Across all designs, the randomized response strategy permits statistical estimates of aggregate parameters without revealing anything definitive about individual respondents. Even without individual-level scores, however, virtually any type of MULTIVARIATE technique usually calculated from individual scores can still be performed. CORRELATIONS and other statistics based on ASSOCIATION can be estimated by treating randomized response data as a special case of MEASUREMENT ERROR with known (or estimable) distributional properties.

In the years since its introduction, randomized response has been successfully applied in many areas of social science to obtain estimates of sensitive behaviors, such as academic cheating, abortion, organizational wrongdoing and whistle-blowing, the use of questionable business practices, sexual aggression, child molestation, AIDS-risky sexual behaviors, substance use, and other forms of criminal activity (see Daniel, 1993, for a review).

Despite its statistical appeal, the randomized response technique has not exactly been embraced by the applied research community. Although the technique is mathematically sound, concerns have been raised over respondents' understanding and trust in it. Yet several field validations have shown promising results. A number of studies have tested performance of the randomized response technique against known data as well as compared estimates obtained using randomized response with results of other relevant methods, such as direct questioning (see Armacost, Hosseini, Morris, & Rehbein, 1991; Stem & Lamb, 1981; Tracy & Fox, 1981; van der Heijden, van Gils, Bouts, & Hox, 2000). The randomized response technique has consistently been shown to outperform

conventional interviewing techniques, yielding higher estimates of occurrence of socially undesirable or illicit behavior.

Although the randomized response technique has been shown to be effective in reducing response bias (tendency to give untruthful answers), there has been mixed evidence as to whether this technique helps to reduce NONRESPONSE BIAS (refusal to participate). Respondents may feel more comfortable answering questions honestly when no one knows which question they are answering, but their perception of the technique as too complicated or laborious may be reason to refuse participation. In the final analysis, randomized response techniques may be most appropriate for relatively sophisticated populations—with respondents able to comprehend and appreciate the protection afforded them through the technique. Even then, some respondents may be as concerned about the impact of their responses, even in the aggregate, on the reputation of their organization or profession as they are about their own privacy.

There are some important considerations for successfully employing the randomized response approach whenever it is used. First, sample sizes must be relatively large to counterbalance the increased uncertainty (i.e., SAMPLING ERROR) that derives from the random error infused by the technique. Second, because of the increased error, the technique is not recommended for investigating rare events, particularly those with prevalence less than 10%. Despite these precautions, there are still certain social science inquiries so delicate that a method like randomized response is simply indispensable.

RANDOMNESS

In statistics, randomness is the fundamental concept on which STATISTICAL INFERENCE is founded. With the proper presence of randomness, we can perform HYPOTHESIS TESTING and construct CONFIDENCE INTERVALS for unknown parameters.

Randomness exists when it is not possible to predict the outcome of an experiment or observation before it is performed.

The concept itself has a broader presence than how it is used in statistics. Simple examples of the presence of randomness include gambling, tossing a coin or a die, and playing cards. Before a coin is tossed, we cannot tell whether heads or tails will show. This leads to “coin toss” becoming a RANDOM VARIABLE with two values, unless we are exceptionally good at tossing coins. Most dependent variables in statistical analyses are random variables.

The opposite of a random variable is a variable where the values are fixed. Most INDEPENDENT VARIABLES are thought of as variables with fixed values. We consider education (say, years of schooling) as fixed. At the same time, income is considered a random variable. It is only with random sampling that we can use people with fixed years of schooling and study the DISTRIBUTION of the incomes for each school year group.

EXPLANATION

In STATISTICS, randomness is required for two things, the collection of DATA and the use of statistical inference. For OBSERVATIONAL data, the elements in a SAMPLE (people, counties, etc.) must be chosen

randomly from the larger POPULATION. A variety of sampling schemes can be used, such as SIMPLE RANDOM SAMPLING, STRATIFIED SAMPLING, and CLUSTER SAMPLING. It is only with random sampling that we can use statistical formulas for the computation of P VALUES or confidence intervals. Those formulas are derived mathematically under the assumption that the data are collected according to proper statistical sampling procedures. Indeed, most formulas in the popular statistical computing packages are only appropriate under the assumption of simple random sampling.

Randomness is also needed for EXPERIMENTAL data. Elements must be assigned to experimental and control groups in a random fashion. A variety of experimental designs exist that guarantee the proper randomness for the data.

HISTORICAL ACCOUNT

References to randomness are found as early as the Old Testament and Viking sagas. They refer to decisions being made by some random mechanism. More extensive studies of randomness started in the 17th century, when gentlemen gamblers wanted to establish rules for payoffs from games of chance with cards and dice. This led to mathematicians developing what we think of today as PROBABILITY theory.

Randomness has its foundations in philosophy of science, and it raises several issues. For example, it can be argued that there are degrees of randomness. The more knowledge we have about a phenomenon, the less random it becomes. In Bayesian statistics, this leads to posterior distributions with decreasing spread.

Also, a person really good at coin tossing may be able to toss a coin in such a way that we can accurately predict for each toss whether it will come up heads or tails. Similarly, in MULTIVARIATE statistical analyses, we can add variables in a REGRESSION analysis and thereby reduce the effect of the residual variable, which is thought to represent the randomness in the dependent variable. If we can add variables such that the MULTIPLE CORRELATION coefficient R becomes equal to 1, then there is no randomness left.

APPLICATION

In the rarified world of vacuum, there is no randomness associated with the time it takes an object to fall a certain distance, and physicists have an equation that relates these variables. With the absence of randomness, the variables are related as expressed in

a natural law. Such laws have often been the envy of social scientists, who have tried to relate variables in similar ways, so far without any success.

Randomness provides the foundation for probability theory. When we do not know the outcome of an experiment or an observation, we try to associate the various outcomes by probabilities. Indeed, it can be said that probability theory consists of the study of randomness. In turn, probability theory provides the foundation for statistical inference.

How do we create randomness and thereby collect random data? This is easier said than done. Samples have to be drawn using methods such as simple random sampling or maybe multistage stratified sampling, based on random numbers. An extreme example of the lack of randomness occurred in the first draft lottery during the Vietnam War, where the selection of birthdays was not random, and young men born later in the year became more likely to be drafted than those born earlier in the year.

EXAMPLES

How do we know that random numbers truly are random? What do we mean by a set of numbers being a random set of numbers? If random numbers were used only for the drawing of random samples, this may not be a very important question. But random numbers are also used in other connections, most importantly in cryptographic work for the construction of secret codes. Also, state lotteries make use of randomness, and anything less than random winning numbers would not be acceptable by the public.

This means that computer scientists and others have given much thought to how to create collections of random numbers as well as trying to determine what it means to have a truly random collection of numbers. The procedure should be such that if we generate a second series of random numbers, we should get a different series of numbers. But most computer programs depend on the so-called seed number to generate random numbers. If we use the same seed number a second time, we get the same collection of numbers, meaning they are not random. Also, each digit should appear about as often as the other digits. But if all sequences of digits are equally likely, we could get a sequence of, say, all 2s. Even though it was generated randomly, we would hesitate using such a sequence for anything.

Humans are not very good at predicting the future, even just the next few minutes. This implies that we find

ourselves living in a random world. To make sense of this randomness, we try to discover regularities in the randomness and thereby create some degree of order.

RANGE

Range is the distance between the extreme high and low values of a VARIABLE. For example, suppose the variable is age, and the youngest person in the study is 26, the oldest 93. Then, the range of the age variable is 26 to 93, or 67 ($93 - 26 = 67$). The range is a quick first measure of the DISPERSION of a variable. However, it should not be used as the last measure of dispersion, because it is unduly influenced by OUTLIERS. In our example, suppose the next highest age after 93 was 61. The presence of the 93-year-old made the range great, perhaps suggesting there were many more very old people than there actually are.

—Michael S. Lewis-Beck

RANK ORDER

Rank order refers to a property of a set of scores such that the scores are ordered from lowest to highest, or, alternatively, from highest to lowest. The scores 15, 14, 8, 11, 12 can be placed into rank order by ordering them from lowest to highest as 8, 11, 12, 14, 15. These scores can be rank ordered from highest to lowest by putting them in the order 15, 14, 12, 11, 8. Stated more formally, a set of scores is rank ordered from lowest to highest if, for any given score X_j , it is always the case that $X_{j-1} \leq X_j \leq X_{j+1}$. Scores are rank ordered from highest to lowest if, for any given score X_j , it is always the case that $X_{j-1} \geq X_j \geq X_{j+1}$.

Sometimes, scores are assigned a rank based on their rank order. Ranks are consecutive, ordered numbers (usually integers) in which the number reflects the relative position of a score in a set of scores that is in rank order. For example, the scores 8, 11, 12, 14, and 15 might be assigned the following ranks:

Table 1

Score	Rank
15	5
14	4
12	3
11	2
8	1

A rank of 3 means that the score is the third highest score relative to the lowest score when scores are assigned ranks where the lowest score receives a rank of 1. A rank of 4 means the score is the fourth highest score relative to the lowest score. Sometimes, scores are assigned ranks whereby the highest score has a rank of 1 and the lowest score has a rank of N , where N is the number of scores being ranked.

The same score may appear twice in a set of scores, such as 8, 11, 15, 14, 8, 12. These scores can still be rank ordered from lowest to highest as 8, 8, 11, 12, 14, 15, or from highest to lowest as 15, 14, 12, 11, 8, 8. When assigning ranks to duplicate scores, the tradition is to assign a rank value that is the average of the ranks, as follows:

Table 2

Score	Rank
15	6
14	5
12	4
11	3
8	1.5
8	1.5

where the rank assigned to the two values of 8 is based on $(1 + 2)/2 = 1.5$.

—James J. Jaccard

RAPPORT

Rapport refers to the situation in interviewing when the interviewer and the interviewee feel comfortable and are in tune with each other. A rapport suggests each knows what the other is saying.

—Tim Futing Liao

RASCH MODEL

The Rasch model is a specific and structurally simple model in the family of ITEM RESPONSE models. The BINARY response [e.g., correct (score 1), incorrect (score 0)] to an item depends on a person's latent trait value and the difficulty of the item. The function that defines the relationship between a 1 score and the latent trait is logistic, with a unique location (difficulty) parameter for each item, but the same discrimination power.

—Klaas Sijtsma

See also ITEM RESPONSE THEORY

RATE STANDARDIZATION

Social scientists have been, more or less explicitly, comparing rates since they opened their eyes to the empirical world. But it wasn't until the late 1800s and early 1900s that scholars began to take seriously, and attempt to adjust for, the observed differences in rates that may be due to differences in the distribution(s) of some CONFOUNDING factor. For example, we may be interested in comparing some crime rate between two locales. If these two locales differ significantly in their age DISTRIBUTIONS, and if the crime rate in question is known to vary by age, then the crime rates will necessarily vary across the two locales to the extent that the age distributions are different. That is, any observed difference in the crime rates would necessarily be due in part to the differences in the age distributions. Moreover, that part of the difference in their rates could not be attributable to any difference in what may be considered the intrinsic nature of the locales facilitating or inhibiting crime. This, of course, has obvious consequences when informing any related social

policy. When comparing rates, therefore, an important question is, To what extent are observed differences in rates due to what are often called *compositional differences* across the populations being compared?

In the first half of the 20th century, part of the solution to this difficult question was to consider what the difference between two (or more) rates would have been if the populations being compared had the same composition (however defined, but frequently in terms of age, race, and/or sex distributions). To do this, researchers often would take as the standard compositional distribution(s) from one population, which could be one of the populations being compared or some other population external to the study. Rates for the remaining comparison population(s) were then calculated in such a way as to adjust, or control, for the compositional differences between the remaining population(s) and the standard population. These adjusted rates are referred to as *standardized rates*. Standardized rates are, to use current language, COUNTERFACTUAL. That is, they are not observed, but rather constructed so that they would have been observed had the compositional distributions been the same as the so-called standard. Thus, any difference in the standardized rates cannot be due to differences in compositional distributions across comparison populations.

Comparisons of the differences in the standardized (counterfactual) rates with the differences in the unstandardized (observed or crude) rates were used by researchers in the early part of the 20th century to calculate that portion of the observed difference due to compositional differences (see, e.g., Groves & Ogburn, 1928). But these applications remained rather informal until the late 1940s and early 1950s, when Evelyn Kitagawa and her colleagues at the University of Chicago formalized this comparison. This technique, published in 1955 by Kitagawa and referred to then as the "components of a difference between two rates" (Kitagawa, 1955, p. 1169), constituted a significant breakthrough and showed precisely how differences in observed crude rates were functions of, for example, compositional differences and composition-specific observed rates.

Since Kitagawa's (1955) fundamental publication, many scholars have added useful methodological advances to our understanding of rate standardizations and comparisons. Among the most important is Clogg's (1978) use of LOG-LINEAR MODELS to develop general methods for what he termed *purging rates* of confounding effects. Clogg's (1978) purging

method—along with elaborations and extensions developed in Clogg and Eliason (1988); Liao (1989); Xie (1989); and Clogg, Shockey, and Eliason (1990)—provides a powerful modeling approach, with foundations in the apparatus of statistical inference, to compare observed, standardized, and, more generally, purged rates, as well as functions of these rates.

RATIO SCALE

S. S. Stevens (1946) described four levels of measurement ranging from least to most precise: nominal, ordinal, INTERVAL, and ratio. Nominal, ordinal, and interval scales are described elsewhere in this volume.

Ratio scales share several common characteristics with interval scales. They distinguish greater and lesser amounts. Intervals between any two adjacent numerals indicating quantities are equal in size.

The distinguishing characteristic of ratio scale is the existence of an absolute origin or zero point. This zero allows the researcher to make explicit how much greater or smaller one quantity is than another. Such statements are not possible with interval scales. [Others argue that the distinction between interval and ratio measurement is of no consequence (Wright, 1997).]

For example, my weight is 180 pounds. My wife weighs 120. We could say, in comparing the two of us, that I am the heavier individual, an ordinal level

distinction. Or, it is possible to state that I weigh 60 pounds more than my wife, a result of the interval-level measurement of weight. Or, I could indicate that weight is a ratio variable by asserting that I am 1.5 times heavier than my wife (and twice as heavy as my 90-pound son). On the other hand, if we were to compare today's cold 30-degree temperature to yesterday's warm 60-degree day, it is possible to claim it is 30 degrees colder today (if we're measuring temperature in Fahrenheit degrees), but we certainly couldn't claim that it is half as warm.

A more subtle way of distinguishing the levels of measurement is to identify the nature of invariance implied by each. Ordinal scales may be subject to MONOTONIC transformations and retain the information in their original scale. Interval scales may be LINEARLY TRANSFORMED. Ratio scales may be transformed only by a CONSTANT. That is, they retain their original information only when subject to multiplication by a constant term ($X' = aX$). Only under this unique situation do ratios remain the same. If I gained 180 pounds (doubling my weight) and my wife gained 120 pounds (getting heavier by a factor of 2), we would retain the same ratio of weight (1.5).

Conventional wisdom has accepted Stevens's argument that certain statistical procedures are appropriate for data at each LEVEL OF MEASUREMENT. For example, the only measure of CENTRAL TENDENCY appropriate for nominal data is the MODE, whereas MEDIANS can be used to describe ordinal data, and arithmetic MEANS are applicable if the data are measured on interval scales.

Ratio-scaled data seem intrinsically valuable, but in many instances, social scientists do not aspire to such precision. Exploratory studies often focus on nominal and ordinal levels of measurement of phenomena of interest. Most CORRELATIONAL/causative studies seek interval-level data. The most common assertion for ratio data comes with the examination of models with INTERACTION terms. A natural origin provides for a fixed interpretation of these terms not always possible with interval-level data centered at arbitrary zero points.

Despite apparent common acceptance of Stevens' typology of levels of measurement—at least as a didactic tool for teaching undergraduates—considerable disagreement surrounds his prescription that level of measurement proscribes the use of certain statistics (Baker, Hardyck, & Petrinovich, 1966; Borgatta & Bohrnstedt, 1980; Gaito, 1980; Mitchell, 1986; Townsend & Ashby, 1984; Velleman & Wilkinson, 1993).

A middle ground might be to recognize that level of measurement is not an innate characteristic of the object being measured. That is, the same measurement of an object may well be treated as representing any of the levels of measurement identified by Stevens. Similarly, once we recognize the likelihood of ERROR—SYSTEMATIC or RANDOM—in any measurement, we can find ourselves less likely to assert strict adherence to a specific level of measurement as a defining characteristic of an object. The measuring instrument also plays a role in establishing the level of measurement of any phenomenon under study.

Stevens' taxonomy of measurement, although the most common, is not the only existing classification scheme. Mosteller and Tukey (1977) and Chrisman (1997), for example, offer a number of additions and modifications to Stevens' taxonomy. Most important about these alternatives is not that they are necessarily better or worse, but rather that they make it clear that Stevens' categorization is not exhaustive.

RATIONALISM

This term refers both to a general philosophical position and to a group of theories of human action and social relations. The long-standing opposition in Western philosophy between rationalism and EMPIRICISM was over whether our knowledge originates in reason or experience, or which of them has priority. In modern philosophy of science, rationalists claim that laws of science are necessarily true, and this idea of necessity sometimes brings them close to REALISM and its account of CAUSALITY. Rationalism is, however, used more often to refer to the principle that humans mostly act or can be assumed to act for good reasons, and that social explanations should be in terms of (usually individual) rational action. This generates a powerful research program in economics and the other social sciences: If we know that it is rational to sell something for the highest price, we can predict that, other things being equal, people will do this. As the philosopher Martin Hollis (1977) put it, “rational action is its own explanation” (p. 21): It is only when people fail to act rationally that we require a special explanation of their conduct. There are, of course, different levels of rational explanation: It is rational to buy cigarettes at the cheapest price, but irrational to smoke them at all. Rational action and rational choice are not necessarily self-interested; people may rationally choose to travel by train rather than car or plane because it causes less environmental damage.

There is substantial disagreement over the usefulness of rational action and rational choice explanations, although they have become increasingly prominent in political science and international relations and can even be found in sociology and social anthropology. Are we really as calculating in our choices of, say, marital partners, political parties, or religions as the model suggests? Rational action theories may seem to ignore the rich texture of human cultures and ideologies. On the other hand, they have given social science some valuable tools and explanatory paradigms, such as the “Free Rider,” the PRISONER’S DILEMMA, and

other models from GAME THEORY. More generally, an understanding (see VERSTEHEN) of the ways in which people understand their situations and the reasons why they act as they do is a central element in social inquiry, even if it is ultimately supplemented or sidelined by more structural explanations. It is worth remembering that we are most often asked to “explain ourselves” when we are thought to have done something wrong.

RAW DATA

Often, we lament, “So much to do, so little time.” The same complaint applies to DATA. Frequently, we find ourselves with “so much (raw) data, and so little (useful) information.” The challenge for most researchers who collect and analyze data is to extract useful information from the raw materials with which they start.

Let’s begin with a series of distinctions necessary to describe raw data.

First of all, “data” is a plural noun. Data are multiples of individual datum.

Second, all collections of data are incomplete. Data are uncollected because of a variety of constraints. Time, money, and their combination, efficiency, are three common reasons we fail to collect all available raw data to answer any question. Increasingly, however, data collection has become easier and more efficient, and more and more data are collected. Absent ability to process this additional raw data, more data may not increase knowledge, but enhanced computing power has produced an ability to process more data more efficiently.

Third, the expression “raw data” implies a level of processing that does not meet expectations that these data provide useful information without further effort. “Raw” suggests that the data have not yet been

summarized or analyzed in a way as to release the information for which they were collected.

Fourth, raw data may be collected in alternative representational schemes that affect how the researcher thinks about processing them. Perhaps the easiest way to think about this is to consider the variety of symbolic formats used in computer processing of information. Data are commonly represented in binary, hexadecimal, or decimal number systems, or as (ASCII) text. Data organization is also relevant: Information may be organized as bits, nibbles, bytes, words, and so on.

One individual’s processed data are another’s raw data. The methods by which data are collected and the level of aggregation of the collected data play important roles in determining how the material gathered as raw data is to be analyzed.

Consider, for example, the collection of responses to a series of five SURVEY questions designed to measure public opinion about abortion. The most disaggregated version of these data is the individual responses—typically represented as numbers symbolizing the answers—to each of the five questions. These data might be used by a survey researcher to establish the patterns or consistency of responses of individuals to the survey questions. Such efforts might produce a second level of data in which a SCALE is created to represent the set of responses to the series of questions, with one score assigned to each individual. A third level of data aggregation might be reached by summarizing the individual scale scores for subsamples or groups of the individuals interviewed. A fourth level of aggregation of these data would be to report what Page and Shapiro (1992) call “collective public opinion” and report the average scale score for the entire SAMPLE—usually in comparison to another sample taken from the same POPULATION at a different point in time or to a sample drawn from a different population at the same point in time.

Even more critical than the methodology used to collect data is the RESEARCH QUESTION to be answered or the THEORY to be tested. Raw data must be more (actually less) than simply the set of all information available in the world. What distinguishes raw data from grains of sand? Data must be identified and collected with a purpose. Research questions motivate the collection of some subset of all possible data and the exclusion of other information.

Ultimately, all data should be subject to a variety of assessments, including judgment as to the degree of error contained in the data relevant to the purpose for

which they were collected. Such assessment includes establishing the RELIABILITY and VALIDITY of data as well as justifications for the discarding of data and consideration of the problem of MISSING DATA.

RC(M) MODEL. See ASSOCIATION MODEL

REACTIVE MEASURES. See REACTIVITY

REACTIVITY

The term *reactivity* simply means that measurements or observations of behavior may influence the behavior, thereby making interpretations subject to error. The reactivity problem can thus be understood as one facet of the wider problem of research artifacts (Rosnow & Rosenthal, 1997), which may be manifested in different ways. For example, based on analyses of filmed interactions between experimenters and research subjects, Robert Rosenthal (1966) observed that experimenters smiled more at female than male subjects, which he whimsically interpreted as suggesting that “chivalry is not dead in the psychological experiment.” Smiling by experimenters affected the subjects’ responses, which is interesting psychologically but disconcerting methodologically,

Rosenthal cautioned. He attributed biasing effects of experimenters to uncontrolled psychosocial and biosocial factors, but he pointed out that experiments with nonhuman subjects are susceptible to reactivity effects as well. For example, he mentioned the finding that experienced observers in an animal laboratory were able to guess which of several experimenters had been handling a rat from the animal’s behavior while running a maze or when being picked up.

In research in which self-report personality measures are used, the reactivity problem is sometimes manifested as SOCIAL DESIRABILITY BIAS, meaning that respondents are reluctant to reveal their true feelings or beliefs, but instead respond in ways they think will elicit favorable impressions of themselves. One standard method for identifying this type of bias is to correlate responses on the personality measures and a measure of social desirability. There is now a body of research and theory on self-report measures, including procedures for detecting and, sometimes, controlling reactivity (Stone et al., 2000).

Another distinction is that made between *reactive measures* and *nonreactive measures*, the latter referring to measures that do not influence behavior (Webb, Campbell, Schwartz, Sechrest, & Grove, 1981). Among the various types of nonreactive measures used by social researchers are physical traces, covert instruments, and contrived unobtrusive observations. For instance, Webb et al. cited researchers who had used pictures of art objects depicting how infants and small children were portrayed to study sociohistorical similarities and differences. The use of DECEPTION (e.g., concealed microphones or hidden cameras) frequently raises ethical concerns, but Webb et al. argued that, in most instances of social research, the covert measures used are harmless enough so that they do not raise serious ethical problems. Research employing contrived, unobtrusive observation calls not only for the use of hidden measures, but for some type of manipulation, as in certain FIELD EXPERIMENTS in the social sciences.

REALISM

Realists assert the actual or possible existence of some disputed entity, which may be a subatomic particle, a social structure, or the world or universe itself. Realism as a general philosophical position is often opposed to skepticism, the doctrine that we can never know whether something (or even anything) exists, and to positions that see reference to entities as merely a useful fiction to make sense of observations. Realism tends to be associated with materialism as opposed to IDEALISM, although it is opposed to nominalism about “universals” or the referents of general terms. In this latter sense, it is closer to idealism in asserting the real existence of, say, something called redness as distinct from its instantiation in particular red objects. In modern philosophy of science, realism mainly opposed POSITIVISM and the claim made in logical positivism or logical empiricism that metaphysical questions about the reality of objects, as distinct from our observations of them, are meaningless. More recently, with the eclipse of positivism (see POSTEMPIRICISM), realists, especially those identifying with CRITICAL REALISM, have turned their opposition more to social CONSTRUCTIONISM and POSTMODERNISM. Others, however, combine a realist conception of science with a social constructionist account of human societies.

Arguments for realism fall into two broad classes. First, there are inductive arguments from scientific convergence. Where scientists increasingly agree about explanations that have been refined over many years, it may be reasonable to think that we are getting closer to a true representation of reality. Second, there are arguments of principle based on what is required for science to be possible or meaningful—notably, that the world exists in an ordered and predictable way. In the social sciences, both sets of arguments are more problematic: There is less convergence on agreed PARADIGMS and not even complete agreement on the very possibility of social science (see NATURALISM). Social scientists are more likely to precede their references to social

structures and mechanisms by an implicit “It is as if . . .”

Realism does not entail a commitment to any particular theory of the social world, nor to any particular set of research methods. As an anti- or postempiricist position, however, it plays down the importance of repeated observation and prediction as criteria of explanatory success. Entities that are observable only in their effects, such as magnetic fields and social structures, may interact with others in such a way as to neutralize one another, although theoretical analysis and experimentation may, nevertheless, demonstrate their existence. Here on the Earth’s surface, we are subject both to its gravitational attraction and to the centrifugal force of its rotation; the result is that we mostly stay where we are. Social forces, individual or structural, may interact in a similar way, but again, they are harder to demonstrate to general satisfaction. Antirealists are suspicious of an apparently uncontrolled proliferation of entities, endowed like humans with causal powers (see CAUSALITY), and accuse realists of ESSENTIALISM.

RECIPROCAL RELATIONSHIP

Reciprocal relationship refers to a hypothesized set of relationships in which some event *X* causes a second event *Y*, and vice versa. Several statistical techniques are used to determine whether this is the case, including the *F* RATIO, indirect least squares (ILS), the INSTRUMENTAL VARIABLES approach, three-stage least squares (3SLS), and TWO-STAGE LEAST SQUARES (also known as nonrecursive causal modeling). Reciprocal relationships are common in CAUSAL MODELING, or in structural equation estimation.

Consider the case of two-stage least squares (2SLS), which is a special case of the instrumental variables approach (Kennedy, 1998, p. 165). To perform 2SLS, one must estimate two equations, one after the other. The first equation should “regress each

ENDOGENOUS VARIABLE acting as a regressor in the equation on all the EXOGENOUS VARIABLES in the system of simultaneous equations ... and calculate the estimated values of these endogenous variables” (Kennedy, 1998, p. 165). The second equation should “use these estimated values as instrumental variables for these endogenous variables or simply use these estimated values and the included exogenous variables as regressors in an OLS [ORDINARY LEAST SQUARES] equation” (Kennedy, 1998, p. 165). This approach tests for the possibility of a reciprocal relationship as it individually regresses all endogenous variables on all of the exogenous variables in that system of simultaneous equations and then calculates estimated values to be used as regressors in ordinary least squares.

An illustration of a reciprocal relationship is useful to fully understand this concept. Political scientist B. Dan Wood illustrated how a reciprocal relationship works in his study on environmental politics. Wood argued that federal implementation of environmental laws in the United States that pertain to clean air is dependent upon both national and subnational implementation of these laws (Wood, 1992). He tested this argument via an instrumental variables approach in which he designed his first equation to predict state-level implementation. His second equation took the predicted values from the first equation and used them as an additional INDEPENDENT VARIABLE to predict federal implementation of environmental laws. A reciprocal relationship exists in this case because the level of state enforcements may depend on the fiscal support that the United States’ Environmental Protection Agency provides to state programs, but state activities may also determine the level of these supports (Wood, 1992, p. 50). This reciprocal relationship is important because Wood (1992) had to determine two things to ensure that this reciprocal relationship exists: (a) the effect of the level of federal fiscal support on the level of state enforcements, and (b) the effect of the level of state enforcements on how much federal fiscal support was received by an individual state. Wood (1992) applied an instrumental variables approach and used his results to conclude that a reciprocal relationship exists between the level of state enforcements and fiscal support provided by the Environmental Protection Agency.

RECODE

Recode is a term used to describe the process of making changes to the values of a VARIABLE. Rarely can researchers proceed directly to data analysis after receiving or compiling a data set. The values of the variables to be used in the analysis usually have to be changed first. The reasons for recoding a variable are many, and include the following:

1. There may be errors in the original CODING of the data that must be corrected. A FREQUENCY DISTRIBUTION run or descriptive statistics on a variable can help the researcher identify possible errors that must be corrected with recodes.

2. Data are usually collected to get as much information as possible, but these data often must be recoded to yield more interpretable results. For example, respondents may be asked to report their date of birth in a survey. Recoding these values to age (in years) lets the researcher interpret the variable in a more intuitive way.

3. Recoding is also necessary if some values of a variable are coded inconveniently. For example, surveys typically code responses of “Don’t know” and “Refused” as 8 and 9. The researcher needs to recode these values so they are recognized as missing values by the computer program being used. Leaving these values unchanged would yield misleading results.

4. Another common reason to recode a variable is to make it ordinal in its codes. The respondent’s party identification may be coded 1 = Democrat, 3 = Republican, and 5 = Independent in a survey. This can be recoded as 1 = Democrat, 2 = Independent, and 3 = Republican to make it ordinal.

5. Recoding can also be used to collapse the values of a variable into fewer categories. For example, respondent’s income may have been collected in \$10,000 ranges where 1 = \$0 to \$10,000, 2 = \$10,001 to

\$20,000, 3 = \$20,001 to \$30,000, and so on, for a total of 10 categories. Income can now be recoded into low, medium, and high levels of income, where the old values of 1, 2, and 3 are recoded to the new value of 1 (low income) and the old values of 4, 5, and 6 are recoded to the new value of 2 (medium income), and so on.

6. Another reason to recode a variable is to transform the values of a variable (e.g., a log transformation) to tease out the true nature of the relationship between two variables.

7. Also, if missing values are assigned a number in the original coding, the researcher needs to recode these values to missing before analyzing the data. It is advisable to run a frequency or descriptive statistics on the recoded variable to make sure that the desired recodes were achieved.

RECORD-CHECK STUDIES

Record-check studies obtain the same factual data from two sources, typically a household survey and administrative records of some kind. Most often, the objective is assessment of measurement error in the household survey; such cases are often called validation studies, and the records data are typically presumed to be without error. Occasionally, data from records may replace that reported in the household survey in calculating survey estimates. As described by Machlin and Taylor (2000), the Medical Provider Survey component of the Medical Expenditure Panel Survey is an example of a data replacement record check.

Marquis (1984) and Groves (1989) each provide detailed definitions of validation-type record-check studies. Marquis described a basic typology for record checks in terms of the values obtained for a binary

variable (e.g., the presence or absence of a chronic condition) in a two-by-two matrix. The two sources could agree positively on the presence of the condition (Cell A of the matrix), they could agree negatively (Cell D), or either the records (Cell B) or the survey (Cell C) could be positive and the other negative. A full-design record check would allow quantification of all four cells. In some “reverse record check” studies, records are checked only for survey respondents reporting positively (an “AC” design). In some “forward record check” studies, a survey is conducted only with individuals identified positively in the records (an “AB” design).

An example of a full-design record-check study is described by Edwards et al. (1994), who compared reports of chronic conditions in a study using the U.S. National Household Interview Survey (NHIS) questionnaire with respondents selected from the membership of a staff model health maintenance organization (HMO). They reported on the agreement between the two sources using the kappa statistic and found good to excellent agreement on some conditions (e.g., diabetes and hypertension) but poor agreement on others (e.g., chronic bronchitis, heart murmurs). They also compared the population estimates resulting from each source and found both overreporting in the household survey as compared with the records (e.g., heart murmurs, tinnitus) and underreporting (e.g., dermatitis, heart conditions).

Two limitations of validation-type record checks identified by Groves are (a) that the records are presumed to be error-free, when, in fact, record systems are often subject to the same kinds of errors as surveys, and (b) that household reports and records data must be matched before they may be compared, another process subject to ambiguity and error. In the Edwards et al. study, for example, a “true” medical condition may have been missing from the records because the patient never mentioned it, because it was diagnosed and treated before the patient joined the HMO, or because of error by medical personnel. Matching medical events, as described by Machlin and Taylor for the MEPS, is a probabilistic process because of errors in the matching characteristics, such as name of patient, data of event, type of event, and reason for the event.

RECURSIVE

Many social scientific THEORIES specify models of more than one equation. A recursive system of equations is a type of SIMULTANEOUS EQUATION system where the equations are linked through a causal chain of dependent variables. In recursive models, (a) direction of influence in the model moves only one way (there is no reciprocal causation or feedback loops), and (b) the errors in the equations are not correlated. Both conditions must be met for a system of equations to be considered recursive.

Consider the following recursive system of equations:

$$\begin{aligned}y_1 &= \gamma_{11}x_1 + u_1, \\y_2 &= \beta_{21}y_1 + \gamma_{21}x_1 + \gamma_{22}x_2 + u_2, \\y_3 &= \beta_{31}y_1 + \beta_{32}y_2 + \gamma_{32}x_2 + u_3,\end{aligned}$$

where $\text{COV}(u_1, u_2) = \text{COV}(u_1, u_3) = \text{COV}(u_2, u_3) = 0$.

In the system of equations, ENDOGENOUS VARIABLES are denoted with y s, and EXOGENOUS VARIABLES are denoted with x s. β s indicate the effect of an endogenous variable on another endogenous variable, and γ s indicate the effect of an exogenous variable on an endogenous variable. Errors in the equations are indicated by u s.

The model can be drawn as a PATH DIAGRAM, which visually presents the relationships between the variables (see Figure 1).

The MODEL can also be represented as MATRICES of coefficients. Note that the subscripts in the equations

Figure 1

above denote the position of the coefficient in the matrix.

$$\begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 \\ \beta_{21} & 0 & 0 \\ \beta_{31} & \beta_{32} & 0 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} + \begin{bmatrix} \gamma_{11} & 0 \\ \gamma_{21} & \gamma_{22} \\ 0 & \gamma_{32} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix}.$$

As in all recursive systems of equations, the above model can be viewed in causal sequence (y_1 affects y_2 , y_1 and y_2 affect y_3), and the disturbances for one equation are uncorrelated with the disturbances from the other equations. Formally, in recursive models, **B** may be written as a lower triangular matrix (coefficients appear only below the diagonal) and the variance-covariance matrix of the errors in the equations (u s) is a diagonal matrix. If there was any reverse causality in the model, such as an effect of y_3 on y_1 (either directly or through a chain of other variables), or if any or all of the errors were correlated, then the model would be NONRECURSIVE.

Each equation of a recursive model can be estimated separately using ORDINARY LEAST SQUARES (OLS) regression.

REDUCTIONISM

In philosophy of science, the term *reductionism* is used in a general sense to indicate the view that complex explanations can or should be reduced to simpler ones—for example, that biological phenomena can be explained by their chemical constituents, which in turn can be explained by their atomic or subatomic properties. In social science, reductionism operates at different levels but follows the same principle of seeking an explanation of complex phenomena in terms of simpler ones. It is a controversial strategy, and those who pursue it rarely use the term, preferring (for example) descriptions such as *METHODOLOGICAL INDIVIDUALISM*.

Reductionism is usually a more radical strategy than individualism and can apply to a wide range of phenomena. It has been pursued in most social sciences, particularly economics, politics, anthropology, and sociology. The approach might be illustrated by the contemporary revival of the Victorian passion for reducing explanations of social phenomena to individual, inherited biological characteristics. This has found its modern expression in the discipline of evolutionary psychology. The extent to which the biological can be said to determine the social, or the form it takes, differs widely among the proponents of an evolutionary approach, but the most common form taken is that of explanations that depend on genetic inheritance.

There are two components to this approach—the genetic one, which moves beyond the more established view that our genetic inheritance can predispose us to certain biological traits (diseases such as cancer, for example), to one that says our genes are wholly or partly responsible for psychological characteristics such as intelligence, or particular forms of behavior such as deviance, spatial ability, sociability, and so on. Second, evolutionary psychologists maintain that genetic makeup results from natural selection in the human species. The Darwinian principle of natural selection rules out the transmission of learned characteristics to offspring; therefore, only reproductive transmission can pass on the genes that lead to biological and behavioral traits. Humans have changed little in physiological terms since the beginning of civilization, specifically in brain capacity and characteristics. Therefore, it is said to follow that our contemporary genetic endowment was shaped at a time when our brains were evolving differently from our

primate relatives. The explanation does not rule out environmental interaction, but it is argued that if we want an explanation for human behavior, we must look to the genetic inheritance of behavioral traits first established precivilization.

Reductionist explanations such as these have led to some very controversial social research. Most notorious is Herrnstein and Murray's *The Bell Curve* (1994). Their central argument was that the majority of America's social and economic problems are the result of low intelligence among those who suffer poverty, unemployment, and educational failure. Thus, it follows that no amount of social intervention—HeadStart programs, for example—can make much difference to the life chances of the individuals and, by extension, the social milieu in which they live. Their argument rests on an analysis of IQ data, from the National Longitudinal Survey of Youth, that they claim demonstrated that IQ tests were a reliable predictor of life success (Dickens, 2000, p. 67). Their research has been criticized both for the weakness of the correlations that led to these conclusions and for the normatively derived definition of IQ.

More generally, critics of biological reductionist approaches focus on the weakness of the data supporting the arguments and the tendency to introduce auxiliary hypotheses to explain empirical contradictions (Dupré, 2001, p. 68). However, the challenge for those in the social sciences, who dismiss *any* biological antecedents for behavior, is to explain how social behavior developed independently of biology.

REFLEXIVITY

Reflexivity is a term that is used in a variety of ways (see Bourdieu & Wacziarg, 1992; Lynch, 2000). For some writers, such as Mead and Garfinkel, reflexivity is a central feature of human social life, although what

they mean by the term differs. For Mead, an individual becomes a self by being able to take the attitude of others and thereby reflect on his or her own behavior (see SYMBOLIC INTERACTIONISM). For Garfinkel, reflexivity refers to the fact that social actions are essentially accountable, in the sense that they are what they are only in and through what they are displayed and read as being by members (see ETHNOMETHODOLOGY). Other usage of reflexivity, and the main focus here, refers to a feature of social research practice, both an existential fact about it and something that can and should be made a virtue. It is argued that researchers are always part of the social world they study; they can never step above it in order to gain an Olympian perspective or move outside it to get a “view from nowhere.” It is taken to follow from this that they should continually reflect on their own role in the research process and on the wider context in which it occurs. This kind of reflection should guide the course of research; and in writing up their findings, it is argued, researchers ought to give a detailed account of the research process so as to allow readers to judge their findings in context (e.g., see Hammersley & Atkinson, 1995).

Several arguments are offered in favor of researcher reflexivity, some of which are incompatible with one another. The most fundamental and straightforward is that research is a complex and difficult activity that cannot be reduced to following a set of preestablished rules. Rather, deciding how best to do it requires continual reflection on what has been done, how successful it has been, and how best to pursue it further. This is a relatively uncontroversial idea. A more developed version of this argument is that the researcher must reflect on how he or she has influenced the situation and the people being studied in order to monitor REACTIVITY, so as to minimize any distorting effect on the research findings.

Another argument for reflexivity demands that sociological theory be applied to social research itself. An example would be Becker’s application of labeling theory to the issue of research BIAS (Becker, 1967). A rather different one is Gouldner’s “reflexive sociology,” where sociology is seen as a transformative social movement that is continually building, applying, and developing an understanding of the world (and of itself) that can facilitate the realization of collective human goals (see Gouldner, 1973).

Other interpretations of reflexivity are linked with skeptical EPISTEMOLOGICAL ideas. The starting point

here is an insistence that knowledge is never simply a representation of what exists but always amounts to a social construction, and therefore reflects the perspective and social location of the researcher. Some versions of this argument are committed to the idea that through reflexivity, research can be made a transparent activity that generates genuine knowledge (see Alvesson & Skoldberg, 2000). For others, the virtue of reflexivity lies entirely in its continual subversion of any tendency to believe that accounts can represent the world. Here, reflexivity amounts to an ethical or political commitment to continually remind readers that all accounts, even including those of the constructionist researcher, are constructions rather than representations (see Woolgar, 1988). From this point of view, accounts cannot be judged in terms of VALIDITY, at least not conceived as correspondence to reality, but must instead be assessed according to political, ethical, or aesthetic criteria. In fact, the primary criterion may simply be how reflexive the researcher has been.

On the basis of all these arguments, reflexivity, albeit conceived in different ways, becomes the key virtue in research and, in some cases, the only possible one. However, there has been criticism of this idea, and there have also been disputes among those advocating different interpretations of reflexivity, or even purportedly operating within the same approach (see Czyzewski, 1994). Some criticism has come from both EMPIRICIST and antiempiricist directions, such as ethnomethodology (see Lynch, 2000). On one side, it is argued that reflecting on the course of the research process does nothing, in itself, to increase the likely validity of the findings. On the other side, some ethnomethodologists criticize this notion of reflexivity for itself implying that researchers can somehow rise above the reflexively constituted world of which both they and what they are studying are necessarily part.

Other criticism has rejected the idea that reflexivity can provide a basis for some single, comprehensive understanding of the social world in the way that, for example, Gouldner proposes (see Hammersley, 1999). Concerns have also been expressed about the consequences of requiring that researchers be reflexively accountable. In particular, it has been suggested that this may expose junior researchers to surveillance that could amount to a form of domination (Paechter, 1996; Troyna, 1994).

The term *reflexivity* is open to a variety of interpretations, then, and although particular versions have been strongly advocated by some as an important part of

postpositivist social research methodology, their value has been challenged by others.

REGRESSION

Regression is the most widely used data analysis technique in the nonexperimental social sciences. In a regression model, a DEPENDENT VARIABLE, commonly labeled Y , is a function of one or more INDEPENDENT VARIABLES, commonly labeled X_1 , X_2 , and so on. The independent variables are assumed to explain, or at least predict, the phenomenon measured by the dependent variable. The simplest of regression models posits only one independent variable: $Y = a + b_1X_1 + e$. This bivariate regression says variable Y is a linear additive function of variable X_1 , plus a constant (the fixed value represented by a) plus error (represented by e). Of principal interest is the influence of X_1 on Y , the regression coefficient represented by b_1 . To obtain numerical estimates for the values a and b_1 , a straight line is fitted to the observations on X_1 and Y by the

method of ORDINARY LEAST SQUARES (OLS). A more complicated regression model posits two independent variables: $Y = a + b_1X_1 + b_2X_2 + e$. This multiple regression model says Y is a linear function of X_1 and X_2 (plus a constant term and an error term). A MULTIPLE REGRESSION ANALYSIS equation always has two or more independent variables. Below, the mechanics of bivariate and multivariate regression are reviewed in a DATA example. Then, assumptions, history, and recent developments are considered.

BIVARIATE REGRESSION

Social scientists often want to examine the relationship between two variables. To illustrate, an empirical example is unfolded. Imagine that educational sociologists in a small midwestern college seek information on the annual earnings of their students well after graduation. They want to know many things, including the influence of basic demographic forces, such as the socioeconomic background of the students' families. In particular, they seek to establish the link, if any, between the educational attainment of parents and the later job earnings of the child. To gather the necessary data on these and other research questions, they draw a RANDOM SAMPLE from the alumni list of 350 students who graduated 15 years ago. Because of cost considerations, they sample 1 out of 10, yielding a sample size of 35. Table 1 contains some of the data from the survey administered to them. In column 1 is the CODE number given the student. In column 2 is the parent education variable, measured as the number of years of formal schooling completed by the most educated parent (mother or father). In column 3 is the student income variable, measured as the reported gross annual income (in thousands of dollars) the student earned 15 years after graduation. In column 4 is the gender of the student, scored 1 = male or 0 = female. These data are listed as they would appear when entered into a typical computer STATISTICAL PACKAGE.

The research question at hand is whether parent education (variable X_1) helps account for later student income (variable Y). The dominant HYPOTHESIS is that they are positively related. The more educated the parental environment, the more child opportunities and incentives for learning and advancement and, ultimately, higher income on the job. Does an analysis of the data support the hypothesis? In bivariate regression, the first step is inspection of a SCATTERPLOT, as in Figure 1.

Table 1 A Data Set of Three Variables

	Variable 1	Variable 2	Variable 3
Case	Schooling	Income	Gender
1	6	18	0
2	6	30	0
3	8	21	0
4	8	24	0
5	8	33	1
6	9	27	0
7	9	30	0
8	10	36	1
9	10	45	1
10	10	21	0
11	11	35	0
12	11	45	1
13	11	31	0
14	11	30	1
15	11	36	0
16	12	42	0
17	12	51	1
18	12	54	1
19	12	38	1
20	12	46	0
21	12	42	1
22	13	39	0
23	14	52	1
24	14	39	0
25	15	57	1
26	15	49	1
27	16	60	1
28	16	47	0
29	16	59	1
30	16	54	0
31	17	61	1
32	17	53	1
33	18	47	0
34	19	67	1
35	20	75	0

Each dot, or point, in the plot represents the scores of a particular student on variables X_1 and Y . For example, student number 35 has a parent education score of 20 years and an income of \$75,000. She is represented by the dot in the upper right-hand corner. Indeed, the point for each student locates itself at the intersection of an imaginary perpendicular line from his or her Y value (on the vertical axis) and of an imaginary perpendicular line from his or her X value (on the horizontal axis). Visual inspection of the scatter of points suggests that X_1 is positively related to Y ; that is, lower values of X_1 tend to appear in the lower left-hand corner with lower values of Y , higher values of X_1 tend to appear in the upper right-hand corner with higher values

**Figure 1** Scatterplot With Regression Line

of Y . Overall, the constellation of dots, to the extent it suggests any geometric form, suggests a linear one. Put another way, a straight line would seem able to touch more of the points than any plausible curve. The formula for a straight line is $Y = a + bX$. The letter a is the CONSTANT value, where the line intercepts the y -axis, and the letter b denotes the SLOPE of the line. In Figure 1, a straight line is actually fitted to this scatterplot and expressed in the regression equation, predicted $Y = 0.88 + 3.35X_1$.

The regression line in Figure 1 is not arbitrarily drawn. Rather, it is the line of best fit, calculated from the LEAST SQUARES principle. Observe that some points fall on the line, and others do not. One sees positive errors (above the line) and negative errors (below the line). If all these errors (measured as the vertical distance of each point to the line) were simply added up, they would sum to zero, with the signs (+ and -) canceling out. However, when these errors are squared, there is no canceling out, and a measure of total error is produced, the sum of the squares of these errors (SSE). The sum of these squared errors is "least," the lowest possible value, hence the phrase "least squares." From calculus, the unique values for the intercept (a) and slope (b) that minimize the SSE are derived, and they constitute the ordinary least squares (OLS) solution. In our example, no other combination of INTERCEPT and slope values would produce a line that fit the data so well as the combination (0.88, 3.35) does.

The regression line serves as a PREDICTION EQUATION. Say the symbol for a predicted Y value is $\hat{Y}$, and $X = 12$. Then,

$$\begin{aligned}\hat{Y} &= 0.88 + 3.35X \\ &= 0.88 + 3.35(12) \\ &= 0.88 + 40.2 \\ \hat{Y} &= 41.08.\end{aligned}$$

The model predicts the student should earn about \$41,000 annually, if the highest educational attainment of the parent was 12 years of schooling. Suppose now that $X = 13$.

$$\begin{aligned}\hat{Y} &= 0.88 + 3.35(13) \\ &= 0.88 + 43.55 \\ \hat{Y} &= 44.43.\end{aligned}$$

One observes that when the educational attainment variable went up one year, the predicted value of income went up by 3.35, the slope value. This illustrates the general interpretation of the slope: b indicates the expected change in Y for a unit change in X_1 . The intercept also has a general interpretation: a indicates the EXPECTED VALUE of Y when $X_1 = 0$. When there are no X_1 values at 0, as is the case with these data, the intercept has a mathematical role (it is a constant that must be added to complete a prediction) but no substantive meaning.

The regression line can be used for predictions, but they are not perfect, as the points distant from the line demonstrate. How well the linear model actually fits the data is measured with the R -SQUARED (R^2), which assesses the variation in the dependent variable accounted for by the independent variable. It is a summary statistic ranging from 1.0 to .00. In the example, $R^2 = 0.76$, suggesting parent educational background accounts for 76% of the variation in student income.

MULTIPLE REGRESSION

Analysis with multiple regression extends the foregoing, by allowing for multiple independent variables. This is an important extension, for two reasons. First, a more complete explanation of a phenomenon becomes possible, because multiple causes, predictors, or determinants can be entertained simultaneously. Second, the specific effect of a particular X on Y can be better

understood, because the influence of other, perhaps CONFOUNDING, variables can be removed through statistical controlling. Consider the example. Other factors besides parent education undoubtedly help shape student income. A multiple regression model is in order, to take these other variables into account. There is a measure on at least one of these other variables—gender. Therefore, the revised theory is that student income (Y) is influenced by parent education (X_1) and gender (X_2). Here are the OLS estimates for this multiple regression model:

$$\hat{Y} = 0.44 + 3.12X_1 + 6.9X_2.$$

On the basis of these results, the interpretation is somewhat altered. The impact of an additional year of parent education appears slightly diminished, compared with the earlier bivariate result ($3.12 < 3.35$). This reduction in the slope coefficient can be attributed to statistically “holding constant” X_2 . Furthermore, gender itself seems to have an independent effect on income. Specifically, males can expect to earn about \$7,000 more than females, once parent education differences are controlled for. Overall, the $R^2 = 0.82$, indicating that these two independent variables together account for 82% of the variation in income. This is a boost in the R^2 of six percentage points, moving from the bivariate to the multivariate model (a gain that drops a bit with the ADJUSTED R -SQUARED).

ASSUMPTIONS

Regression analysis of nonexperimental social science data aims to reveal structural links—causal, explanatory, predictive—between variables in the real world. More formally, the goal is to estimate POPULATION parameters, the fixed intercept and slope values that reliably join the variables under study. These estimates are accurate to the extent that key assumptions are met. If the assumptions are ignored, regression results may have no reality beyond the numbers typed on a page. Granting the Table 1 data, do the regression estimates presented reveal the actual connection between student income, parent education, and gender? Yes, to the extent that they are supported by the assumptions presented below.

Most regression analysis is carried out on a SAMPLE, rather than on the target population as a whole. With estimation of the sample equation, say, $Y = a + b_1X_1 + b_2X_2 + e$, inferences are made to the

parameters in the population equation, say, $Y = \alpha + \beta_1 X_1 + \beta_2 X_2 + \varepsilon$. The sample must be a scientific PROBABILITY SAMPLING of sufficient size. Furthermore, because the samples are only samples, SIGNIFICANCE TESTING must be applied, to rule out chance results. For example, with the sample of 35 students out of the population of 350, we observe a slope coefficient of 3.12 in the multiple regression equation. A significance test (.05, two-tailed) applied to that regression coefficient allows us to reject the NULL HYPOTHESIS that the link between parent education and income is zero in the population, that is, $\beta_1 = 0$.

Besides assumptions of proper sampling and significance testing, there are the classical linear multiple regression assumptions, which can be variously stated. Broadly, these include no SPECIFICATION error, no measurement error, no perfect COLLINEARITY, and no error term problems. With respect to specification, the essential ideas are that the model has the right independent variables, and their relationship to the dependent variable is linear. With respect to measurement, the variables should be quantitative and accurately scored. With respect to collinearity, no independent variable is allowed to be a perfect linear function of all the others. With respect to the error term, it should not be related to the independent variables either as variance (to preserve HOMOSKEDASTICITY) or as a variable (because the data are nonexperimental), and it should not be related to itself (to avoid AUTOCORRELATION). When these assumptions are met, the OLS estimator is BLUE, or BEST LINEAR UNBIASED ESTIMATOR. Certain analysts prefer to think of the classical linear regression assumptions as lying along a continuum, say, from 1 to 10, where 1 means *not met at all* and 10 means *perfectly met*. In that view, the closer the results to 10, the closer the inferences are to reality.

OLD DIRECTIONS AND NEW

Sir Francis Galton (1822–1911) can perhaps be considered the founder of regression analysis, because he was the first to perceive that a straight line could make sense of the whirl of points in a scatterplot. He and his disciple Karl Pearson (1857–1936) made extensive investigations of scatterplots relating the characteristics of fathers and sons. For example, Pearson examined the heights of 1,078 father-and-son combinations and found that very tall fathers tended to have shorter sons. This was “to regress toward the mean,” or what Galton called “regression to mediocrity.” The straight

line that depicted this regression effect was named the “regression line.” Modern regression and CORRELATION methods were launched by the papers published on genetics in the journal *Biometrika*, particularly the work of Pearson coming out in 1903.

OLS has been the central method of regression estimation. The least squares method was discovered independently by French mathematician Adrien Marie Legendre (1752–1833) and German mathematician Carl Friedrich Gauss (1777–1855). When the classical multiple regression assumptions are met, OLS estimators cannot be improved upon. A great deal of work, especially since the 1960s, has gone into REGRESSION DIAGNOSTICS, which attempt to test assumptions and provide corrections. However, certain models are intrinsically nonlinear, and their parameters cannot be efficiently estimated with OLS. A case in point is when the dependent variable is dichotomous, say, a “yes” versus “no” vote choice. Here, a MAXIMUM LIKELIHOOD ESTIMATION technique, such as LOGISTIC REGRESSION, is generally preferred. Logistic regression approaches, including POLYTOMOUS ones, have recently been a vigorous area of research. Although these approaches are, in some ways, very far from OLS, the logic of the modeling, and many of the problems of inference due to violation of assumptions, is the same.

REGRESSION COEFFICIENT

The term *REGRESSION* refers to a group of popular methodologies that aims to explain variation in a DEPENDENT VARIABLE (Y) using a set of k INDEPENDENT VARIABLES (X_k). In the context of ORDINARY LEAST SQUARES (OLS), a regression coefficient ($\hat{\beta}_k$) is associated with each independent variable ($X_1, X_2, \dots, X_k$) and gives the expected direct effect of a one-unit change in that independent variable on the dependent variable, holding all other independent variables constant. The regression coefficient is

always expressed in units of the dependent variable. In addition, an INTERCEPT term ($\hat{\beta}_0$) is usually estimated and yields the expected value of the dependent variable if all independent variables were equal to zero.

In OLS estimation with two independent variables (X_1 and X_2) and n observations, the formulas to calculate the intercept and regression coefficients are as follows:

$$\hat{\beta}_0 = \bar{Y} - \hat{\beta}_1 \bar{X}_1 - \hat{\beta}_2 \bar{X}_2,$$

$$\hat{\beta}_1 = \frac{\left(\sum_{i=1}^n (y_i - \bar{y})(x_{1i} - \bar{x}_1) \right) \left(\sum_{i=1}^n (x_{2i} - \bar{x}_2)^2 \right) - \left(\sum_{i=1}^n (y_i - \bar{y})(x_{2i} - \bar{x}_2) \right) \left(\sum_{i=1}^n (x_{1i} - \bar{x}_1)(x_{2i} - \bar{x}_2) \right)}{\left(\sum_{i=1}^n (x_{1i} - \bar{x}_1)^2 \right) \left(\sum_{i=1}^n (x_{2i} - \bar{x}_2)^2 \right) - \left(\sum_{i=1}^n (x_{1i} - \bar{x}_1)(x_{2i} - \bar{x}_2) \right)^2}.$$

Consider the following hypothetical example:

Table 1 Calculation of Regression Coefficients

<i>I</i>	<i>y</i>	<i>x</i> ₁	<i>x</i> ₂	
1	22	39	6	$\bar{y} = 24.6$
2	21	41	22	$\bar{x}_1 = 35.2$
3	24	39	20	$\bar{x}_2 = 14.6$
4	24	34	8	$\sum_{i=1}^n (y_i - \bar{y})(x_{1i} - \bar{x}_1) = -82.1$
5	26	33	21	$\sum_{i=1}^n (y_i - \bar{y})(x_{2i} - \bar{x}_2) = 21.2$
6	32	27	20	$\sum_{i=1}^n (x_{1i} - \bar{x}_1)(x_{2i} - \bar{x}_2) = -31.1$
7	20	31	16	$\sum_{i=1}^n [(x_{1i} - \bar{x}_1)(x_{2i} - \bar{x}_2)]^2 = 967.9$
8	27	32	8	$\sum_{i=1}^n (x_{1i} - \bar{x}_1)^2 = 197.6$
9	25	41	10	$\sum_{i=1}^n (x_{2i} - \bar{x}_2)^2 = 338.2$

Based on these data, and the formulae, we get the following model estimation:

$$\hat{y} = 38.7 - 0.412x_1 + 0.025x_2.$$

The intercept term indicates that if x_1 and x_2 were both zero, we would expect Y to equal 38.7. This may, or may not, have substantive meaning in practical research. The coefficient for x_1 denotes that for every one-unit change in x_1 , we would expect a 0.412-unit decrease in the dependent variable, holding x_2 constant. Similarly, the coefficient for x_2 shows that for every one-unit change in that variable, we would expect Y to increase by 0.025 units, holding x_1 constant. If none of the ASSUMPTIONS of the OLS model is violated, the estimated coefficients are UNBIASED and maximally efficient estimates of the true POPULATION parameters. Additionally, all regression coefficients have associated STANDARD ERRORS that enable us to

test the hypothesis that they are statistically different from zero.

The example illustrates the intuition behind regression coefficients and shows how to calculate and interpret them in a simple model. The calculation procedures and interpretation of regression coefficients are somewhat different in more complicated models, such as models with INTERACTIONS and NONLINEAR relationships between the independent variables, and models with limited dependent variables. In limited dependent variable cases, the regression coefficients are often calculated via MAXIMUM LIKELIHOOD ESTIMATION and cannot be interpreted as having a linear effect on the dependent variable (Greene, 2003). The basic intuition, however, is the same—a regression coefficient tells us how one variable affects another while holding other explanations constant.

REGRESSION DIAGNOSTICS

Common violations of the assumptions of LEAST SQUARES regression are nonlinearity, HETEROSKEDASTICITY, and non-normally distributed error terms. Unusual observations can also have undue influence on the regression equation, and MULTICOLLINEARITY can cause unstable estimates. It is important to perform diagnostics of the model because if these problems are not rectified, OLS estimates are no longer the BEST LINEAR UNBIASED ESTIMATORS.

Nonlinearity in simple regression is easily assessed by examining a SCATTERPLOT of the dependent variable Y against the independent variable X . In multiple regression, however, simple scatterplots no longer suffice because they show only the marginal relationships between Y and each of the individual X s, when the model gives PARTIAL REGRESSION COEFFICIENTS. Partial residual plots (also called component-plus-residual plots) are thus used to assess linearity in the

multivariate case. The partial residual $E(j)$, for the j th independent variable, is simply the linear component of the partial regression of Y on X_j added to the least squares residuals. The $E(j)$ are plotted versus X_j , and linearity is assessed in the same manner as the scatterplot for simple regression.

Nonlinear relationships can be handled by transforming Y and/or X (when the nonlinearity is simple and monotone), POLYNOMIAL EQUATIONS (when the relationship is nonmonotone but has relatively few changes in direction), or LOCAL REGRESSION (when the nonlinear relationship is very complex).

Unusual observations that are OUTLIERS (i.e., have an unusual Y value given their X value) and have high leverage (characterized by an unusual X value) unduly influence the coefficients of a regression model.

Statistical tests for outliers are usually based on the studentized residuals (sometimes called standardized residuals). The “mean shift” regression model—which simply includes a DUMMY VARIABLE coded 1 for the unusual observation and 0 for all other cases—is a commonly used method for finding the studentized residual for an outlier. If the coefficient for the dummy variable is statistically significant, the observation significantly deviates from the pattern of the rest of the data. Nevertheless, because we select the furthest outlier, rather than observations at random, a simple t -test is inappropriate. A Bonferroni adjustment to the p value remedies this problem. The Bonferroni p value for the largest outlier is $p = 2np'$, where p' is the unadjusted p value from a t -test with $n - k - 2$ degrees of freedom.

Leverage is measured by the hat value h_i , which captures how much the observed Y_i affects the predicted value $\hat{Y}$. In simple regression, hat values are determined by $h_i = \sum_{j=1} (X_j - \bar{X})^2$ and are bounded between $1/n$ and 1, with an average of $(k + 1)/n$. Hat values that are approximately twice the average are usually considered noteworthy.

The most commonly used diagnostic for INFLUENTIAL CASES is Cook’s Distance (or, more simply, Cook’s D) which measures the impact of an unusual observation on the slope coefficient. Cook’s D is simply calculated:

$$D_i = \frac{E_j^{*2}}{k + 1} \times \frac{h_i}{1 - h_i}.$$

There is no universally accepted cutoff for Cook’s D, but a loose rule of thumb is that values greater than $4/(n - k - 1)$ should be looked at closely.

When trying to identify unusual cases, it is helpful to examine the data graphically. In the simple regression case, scatterplots are useful. Added-variable plots (also called partial regression plots) are useful methods of assessing joint influence in multiple regression. In all cases, influence plots (also called “bubble plots”)—which plot hat values, studentized residuals, and Cook’s Distances on a single graph—can be particularly useful.

Unusual observations may reflect miscoding, in which case the observations can be rectified or deleted. Sometimes, however, an outlier is of substantive interest, so we may decide to deal with it separately from the rest of the analysis. The presence of many outliers may indicate that an important explanatory variable is missing from the model. If there are no strong reasons to remove outliers, ROBUST regression, which downweights influential data, can be used in place of OLS.

HETEROSKEDASTICITY is usually assessed using a residual plot, which plots the residuals E_i (or studentized residuals, E_i^*) against $\hat{Y}$ (the predicted value of Y). If the values of Y are all positive, we can use a spread-level plot, which plots the $\log|E_i^*|$ (called the log spread) against the $\log \hat{Y}$ (called the log level). The SLOPE, B , of the regression line fit to the spread-level plot suggests the variance-stabilizing power transformation p , for Y , with $p = 1 - B$. If the error variances are proportional to a particular X , WEIGHTED LEAST SQUARES provides a good alternative to OLS.

Non-normality can be diagnosed using quantile comparison plots, which plot the distribution of the studentized residuals E_i^* against the quantiles of the unit-normal distribution or the t -distribution. If the distribution is not skewed, the relationship will be roughly linear. Modality is best assessed using HISTOGRAMS or density estimates of the residuals. Transformations of either Y or the X s can often remedy a heavy-tailed error distribution, whereas model respecification—that is, including a missing discrete predictor—can sometimes fix a multimodal problem.

Multicollinearity can be indicated by a very high pairwise CORRELATION (.8 or higher) between two independent variables, but it is also possible in the absence of high pairwise correlations because it reflects the multiple correlations between each X and all the other X s in the model. It is more effective, then, to

examine the R^2 s for each X regressed on all other X s in the model ($R^2 = .6$ or higher is of concern). Related to the R^2 , the VARIANCE-INFLATION FACTORS (VIF) for each variable, which is defined by $VIF = 1/(1 - R_j^2)$, indicates the impact of collinearity on the precision of the SLOPE, B_j . The square root of the VIF is the factor by which the standard error is inflated because of the multicollinearity.

REGRESSION MODELS FOR ORDINAL DATA

Ordinal-level variables (such as LIKERT SCALES from survey questions, some measures of social class, etc.) are commonly used as DEPENDENT VARIABLES in the social sciences. Such data can be modeled in several ways within a REGRESSION framework: (a) The ordering of the categories can be ignored, allowing the use of binary or MULTINOMIAL LOGIT models; (b) the categories can be treated as though they were measured on an interval scale, enabling the use of ORDINARY LEAST SQUARES (OLS); and (c) models developed specifically for ordinal dependent variables can be used. Each of these methods has strengths and limitations.

The first strategy—ignoring the ordered nature of the dependent variable—is most feasible when there are few categories to the dependent variable. For example, if the categories of the dependent variable can be legitimately collapsed into two categories without losing too much information, simple binary logit models (LOGISTIC REGRESSION) can be used. For these models, ODDS RATIOS can be used to determine

differences between categories. The limitation of this approach, however, is that by collapsing categories, we lose possibly important information about the dependent variable. Although multinomial logit models can be used if we choose not to collapse the categories, these models are inefficient and become increasingly difficult to interpret as the number of categories in the dependent variable rises because of the large number of parameters that are estimated.

The strength of the second strategy—using OLS—is that the parameter estimates are easily interpreted (see SLOPE). OLS can be legitimately used if the distribution of the dependent variable appears to be roughly normal and the ordered categories accurately represent an underlying continuous distribution. If the variable has many categories, a HISTOGRAM can give a rough assessment of the distribution. On the other hand, if the variable is measured using only a few categories, the variable will be characterized by such a high degree of measurement error that this assumption cannot be reasonably assessed. These models can also be problematic if prediction is a main goal of the research, because predicted values outside the range of the variable are possible. Nonetheless, because the variable is knowingly measured with error, having predicted values outside the range of the variable is not necessarily problematic, especially if the research is primarily concerned with determining relationships rather than making predictions.

Because we often cannot assume that the distances between categories of ordered variables are interval—meaning that they do not satisfy the criteria of OLS (in particular, the assumption of constant error variance)—regression models specifically for ordinal data have been developed. These models include the ordered logit model, which is a generalization of logistic regression, and the ordered PROBIT ANALYSIS model, which is a generalization of the binomial probit model. Here, we will deal with the most commonly used of the ordered logit models: the proportional-odds model.

Logits can directly incorporate the ordering of categories in a dependent variable, resulting in a model with a simpler interpretation and potentially greater power than multinomial logit models, which are typically used for unordered categorical dependent variables. Consider a latent continuous variable ξ , which is a linear function of the explanatory variables, the X s, plus a random error:

$$\xi_i = \alpha + \beta_1 X_{i1} + \cdots + \beta_k X_{ik} + \varepsilon_i.$$

Assume here that ξ represents attitudes toward abortion and the β s are the regression slopes. Assume also that we have only a single 5-point LIKERT SCALE to tap attitudes toward abortion, Y . In this case, the latent continuous variable ξ has been divided into five categories, $m = 5$, with $m - 1 = 4$ boundaries, $\alpha_1 < \alpha_2 < \dots < \alpha_{m-1}$:

$$Y_i = \begin{cases} 1 & \text{if } \xi_i \leq \alpha_1 \\ 2 & \text{if } \alpha_1 < \xi_i < \alpha_2 \\ \vdots & \\ m-1 & \text{if } \alpha_{m-2} < \xi_i \leq \alpha_{m-1} \\ m & \text{if } \alpha_{m-1} < \xi_i. \end{cases}$$

The cumulative probability distribution of Y is then easily found:

$$\begin{aligned} \Pr(Y_i \leq j) &= \Pr(\xi_i \leq \alpha_j) \\ &= \Pr(\alpha + \beta_1 X_{i1} + \dots + \beta_k X_{ik} + \varepsilon_i \leq \alpha_j) \\ &= \Pr(\varepsilon_i \leq \alpha_j - \alpha - \beta_1 X_{i1} - \dots - \beta_k X_{ik}). \end{aligned}$$

From these, we can find the ordered LOGIT MODEL:

$$\begin{aligned} \text{logit}[\Pr(Y_i > j)] &= \log_e \frac{\Pr(Y_i > j)}{\Pr(Y_i \leq j)} \\ &= (\alpha - \alpha_j) + \beta_1 X_{i1} + \dots + \beta_k X_{ik}. \end{aligned}$$

Here, the logits are cumulative logits that contrast categories above category j with category j and below it. Only one slope coefficient is found for each X , but there is a separate intercept for each category. The first category (or last, depending on the software) is set as a reference category to which all the intercepts relate.

Coefficients from ordered logit models are interpreted in the same way as for the dichotomous logit model, except rather than referring to a single baseline category, we contrast each category and those below it with all the categories above it. In other words, the logit tells us the log of the odds that Y is in one category and below versus above that category.

Despite the appealing parsimony, the proportional-odds models must be used cautiously. These models assume that the regression slopes are equal (referred to as the proportional-odds assumption or the assumption of parallel slopes), something that does not often hold in practice, especially with large samples. A simple way to test whether this assumption is met is to compare the fit of the model with the fit of the multinomial logit model, which can be seen as a more general case. The difference in deviance of the two models

gives a generalized LIKELIHOOD RATIO test, which is distributed as chi-square with DEGREES OF FREEDOM equal to the difference in the number of parameters between the multinomial logit model and the proportional-odds logit model.

REGRESSION ON ...

The phrase “regression on” refers to the act of projecting the INDEPENDENT VARIABLE vector (sometimes referred to as the “regressand”) onto the Euclidean subspace spanned by the DEPENDENT VARIABLES (sometimes collectively referred to as “REGRESSORS”). Although the phrase refers to the underlying geometry of least squares, it is often used to indicate the set of independent variables used to model the observed variation in the dependent variable.

For example, if a researcher is interested in the simple LINEAR REGRESSION of $Y = b_0 + b_1 X + e_1$, we say that “ Y is regressed on X ”—indicating that the simple regression recovers the set of coefficients $\{b_0, b_1\}$ such that the projection of Y onto the subspace spanned by X (in this case, a line) is given by $b_0 + b_1 X$. Because different values of b_0 and b_1 (say, b'_0 and b'_1) project Y onto the subspace of X differently (i.e., $b'_0 + b'_1 X$), there are (infinitely) many possible projections/regressions. To determine which projection/regression is of most interest, researchers must assess the “fit” according to a given criterion. A commonly used criterion is that of LEAST SQUARES, which denotes the “best” projection as the choice of $\{b_0, b_1\}$ for which $|Y - (b_0 + b_1 X)|^2$ is minimized.

In the MULTIPLE REGRESSION ANALYSIS context, “regression on” refers to the projection of the dependent variable vector into the subspace spanned by the set of independent variables—with the REGRESSION

PLANE defining the plane that minimizes the squared differences between the observed values of the dependent variable and its projection into the regression plane.

REGRESSION PLANE

The regression (hyper) plane represents the projection of the dependent variable into the Euclidean subspace spanned by the independent variables.

MULTIPLE REGRESSION using the LEAST SQUARES criterion involves finding the hyperplane that minimizes the sum of squared differences between the observed values of the dependent variable, and the projection of the dependent variable onto that hyperplane.

The hyperplane that minimizes this difference is called the regression hyperplane.

An example clarifies the concept. Suppose that a researcher is interested in the (linear) relationship between the dependent variable Z and the independent variables X and Y . The equation of interest is therefore

$$Z = b_0 + b_1X + b_2Y + e.$$

Consider the nature of the data being fitted—each observation i defines a point in the three-dimensional space (X_i, Y_i, Z_i) . Intuitively, in the above example, the regression plane is the two-dimensional flat surface that “best fits” the set of three-dimensional data points—where “best fits” means that the regression plane minimizes the sum of squared differences (i.e., residuals) between the surface of the plane (which represents the predicted value of Z given X and Y) and the observed Y . For this example, the regression plane defines the two-dimensional plane that minimizes the sum of squared residuals between the independent variable Z and the plane. More generally, if there are k dependent variables (excluding the constant term), the regression hyperplane is the k -dimensional flat surface

Figure 1 Regression Plane

representing the best linear projection of Y into the $(k + 1)$ -dimensional space spanned by the k independent variables plus the dependent variable. The regression plane is a special case for $k = 2$.

REGRESSION COEFFICIENTS define the slope of the regression plane in the dimension defined by the respective independent variable. For example, in the three-space defined above, b_0 defines the “height” of the regression plane in the third (i.e., Z) dimension when $X = Y = 0$, b_1 defines the slope of the regression plane in the first dimension (i.e., the angle at which the plane intersects the Z - X plane), and b_2 defines the slope of the regression plane in the second dimension (i.e., the angle at which the plane intersects the Z - Y plane). The equation for the regression plane is $b_0 + b_1X + b_2Y$. In other words, just as simple regression involves finding the best fitting line, the generalization to multiple regression involves finding the best fitting plane.

An illustration clarifies. The plane depicted in Figure 1 is characterized by the regression equation $Z = 0.3 - 0.5X + 2Y$. Because the regression plane describes the mapping of Z onto X and Y , it is possible to generate a predicted value of Z for any (X, Y) pair. The regression plane depicts these predictions. The geometric interpretation of the slope coefficients is also evident from the figure. The regression coefficient for X of -0.5 implies that the plane in the figure “tilts” to the left; higher values of X lead to lower predicted values of Z . In contrast, the plane “rises” in the back because the slope coefficient for Y is positive. The intercept (in this case, 0.3) is given by the “height” of the plane when $X = Y = 0$.

REGRESSION SUM OF SQUARES

In LINEAR REGRESSION analysis, it is useful to report how well the sample regression line fits the data. A typical measure of GOODNESS OF FIT for a linear regression model is the fraction of the sample variation

in the response (or dependent) variable (Y) that is explained by the variations in independent variables (X s). Regression sum of squares (RSS) is the key component of a common goodness-of-fit measure for a linear regression model. RSS tells data analysts how much of the observed variation in Y can be attributed to the variation in the X s. In other words, RSS indicates the jointly estimated effect of X s on the variation of Y .

To explain the idea of RSS, it is useful to define SAMPLE variation in the DEPENDENT VARIABLE Y . The observed variation in Y for a specific observation, say, Y_i , is simply its deviation from the mean of Y or, symbolically, $Y_i - \bar{Y}$. Because we are interested in all observations, a convenient summary measure is the sum of squared deviation for all observations. This gives total variation of Y or total sum of squares (TSS):

$$\text{TSS}(\text{Total Variation of } Y) = \sum_i (Y_i - \bar{Y})^2.$$

The question that arises now is how to decompose the total variation in Y , which is also known as “total sum of squares” and denoted by TSS, so that we can measure how much of the total variation in Y can be attributed to the variation in the X s. We can consider the following identity, which holds for all observations:

$$Y_i - \bar{Y} = (Y_i - \hat{Y}_i) + (\hat{Y}_i - \bar{Y}), \quad (1)$$

where $\hat{Y}_i$ is the fitted value of Y for a specific observation with an independent variable that equals X_i . That is, $\hat{Y}_i = \hat{\beta}_0 + \hat{\beta}_1 X_i$ for a SIMPLE REGRESSION model.

We already defined the left-hand side of the equal sign in equation (1) as the deviation of a specific value of Y (i.e., Y_i) from the mean of Y . The first component on the right-hand side gives the RESIDUAL e_i because, by definition, $Y_i = \hat{\beta}_0 + \hat{\beta}_1 X_i + e_i = \hat{Y}_i + e_i$. Thus, $Y_i - \hat{Y}_i = e_i$. The second right-hand term gives the difference between the fitted (or predicted) value of Y and the mean of Y . Because $\hat{Y}_i$ is predicted by using the values of the independent variable (X_i), the second right-hand term represents the part of the variation in Y that is explained by the variation in X . The decomposition of variation in Y for a simple regression (i.e., only one independent variable) is shown in Figure 1.

As noted previously, equation (1) applies for only a single observation. We can obtain a summary measure for all of the data by squaring both sides of the equality

Figure 1 Decomposition of Variation in Y

and summing over all sample observations. This gives the following equation:

$$\sum_{i=1}^n (Y_i - \bar{Y})^2 = \sum_{i=1}^n (Y_i - \hat{Y}_i)^2 + \sum_{i=1}^n (\hat{Y}_i - \bar{Y})^2 + 2 \sum_{i=1}^n (Y_i - \hat{Y}_i)(\hat{Y}_i - \bar{Y}). \quad (2)$$

The last term in equation (2) is identically zero because of two ASSUMPTIONS of a classical normal linear REGRESSION model, zero mean of the disturbance [$E(e_i|X_i) = 0$] and zero covariance between disturbance and independent variables [$\text{cov}(e_i, X_i) = E(e_i X_i) = 0$]. As a result, equation (2) can be rewritten as

$$\sum_{i=1}^n (Y_i - \bar{Y})^2 = \sum_{i=1}^n (Y_i - \hat{Y}_i)^2 + \sum_{i=1}^n (\hat{Y}_i - \bar{Y})^2.$$

Total Sum of Squares (TSS)	=	Error Sum of Squares (ESS)	+	Regression Sum of Squares (RSS)
----------------------------	---	----------------------------	---	---------------------------------

(3)

Equation (3) shows that regression sum of squares (RSS) can be defined as the sum of squared difference between the predicted value of the dependent variable ($\hat{Y}_i$) and the mean of the dependent variable ($\bar{Y}$) for all observations $i = 1, 2, \dots, n$. Equation (3) also shows that the variation in Y is partly due to the effect of random disturbance (i.e., the ESS term) and partly due to the changes in X (i.e., the RSS term).

The proportion of total variation in Y (or total sum of squares, TSS) that can be attributed to the variation in X is a commonly used measure of the goodness of fit, which is known as the (sample) COEFFICIENT OF DETERMINATION and denoted by R -SQUARED (R^2).

Note that R^2 is a nonnegative quantity and cannot be greater than 1 (i.e., $0 \leq R^2 \leq 1$). More information on other properties of R^2 and technical derivation regarding how to obtain equation (3) may be found in Fox (1997); Rawlings, Pantula, and Dickey (1999); Kmenta (1986); and Johnston and Dinardo (1997).

REGRESSION TOWARD THE MEAN

First noted by Francis Galton (1822–1911), regression toward the mean (RTM) is a statistical phenomenon that occurs between any two imperfectly correlated variables. The variables could be either distinct but measured contemporaneously (e.g., height and weight), or the same and measured at different times (t and $t + 1$). In either case, extreme observations on the first variable are likely to be less extreme—that is, closer to the mean—on the second variable. Galton's work focused on the hereditary size of pea seeds and human beings. He found that both “regressed toward mediocrity”; larger parents had slightly smaller offspring, whereas the smaller parents had slightly larger offspring. When RTM is ignored, it is a threat to the INTERNAL VALIDITY of experiments.

RTM occurs whenever two variables are not perfectly correlated ($\rho < 1$). If two variables are STANDARDIZED (both have a mean = 0 and a standard deviation = 1) and NORMALLY DISTRIBUTED, we can use their correlation to estimate the expected RTM:

$$E(Z_Y|Z_X) = \rho Z_X.$$

For example, if the weights of mothers and daughters are standardized, and their correlation is .8, we would expect a mother who was 2 STANDARD DEVIATIONS above the “mother” mean to have a daughter who was 1.6 standard deviations above the “daughter” mean. Importantly, the formula indicates that the expected amount of RTM increases as the correlation between the variables decreases. RTM is also bidirectional:

$$E(Z_X|Z_Y) = \rho Z_Y.$$

So, we would expect a daughter who was 2 standard deviations above the “daughter” mean to have had a mother who was only 1.6 standard deviations above the “mother” mean.

Although the formulas given above are useful for estimating the expected amount of RTM for an individual, RTM is inherently a group phenomenon. Any particular individual may move further from the mean upon second observation, but groups will always regress toward the mean as long as the correlation between the two variables is imperfect. Furthermore, the more extreme a group is, the more it will regress in absolute terms. Groups with means close to the sample mean do not have very far to regress, and the further the group mean is from the sample mean, the more room there is for regression. This has important implications for the internal validity of many social science experiments. Often, subjects are selected because they have performed particularly well or poorly. Especially in the latter case, an intervention may be performed to address the problem, and subjects will almost always show improvement. Given that the group is extreme, however, the improvement may be explicable by RTM alone.

REGRESSOR

Regressor is a term that describes the INDEPENDENT VARIABLE(s) in a regression equation that explain

VARIATION in the DEPENDENT VARIABLE (regressand). The regressor is also known as the EXPLANATORY VARIABLE or the EXOGENOUS VARIABLE. In a system of equations, a variable that is the regressor in one equation may be the regressand in another, thus complicating the use of the term *exogenous*.

A regressor may be a QUANTITATIVE VARIABLE (i.e., measured on an INTERVAL or RATIO SCALE) or a QUALITATIVE VARIABLE (i.e., observed as a nominal or categorical trait). As a matter of convenience in the classical linear regression model, regressors are assumed to be nonstochastic or “fixed in repeated samples.” This assumption may be relaxed with little cost, particularly if the sample size is large.

RELATIONSHIP

A relationship is the connection between two or more CONCEPTS or VARIABLES. If, for example, two variables are related to each other, then they tend to move together in some nonrandom, systematic way. For example, as X scores go up, Y scores tend to go up. This link between X and Y can be quantified in a MEASURE OF ASSOCIATION, decided in part by the LEVEL OF MEASUREMENT of X and Y . The most prevalent measure of association is PEARSON’S CORRELATION COEFFICIENT, which assesses the linear relationship between X and Y , assuming these variables are measured at the INTERVAL level. A relationship can exist between three or more variables. For example, three variables— X_1 , X_2 , and X_3 —can be related to variable Y . If all the variables are interval, then a MULTIPLE CORRELATION coefficient, R , could be calculated to estimate this relationship.

—Michael S. Lewis-Beck

RELATIVE DISTRIBUTION METHOD

Differences among groups or changes in the distribution of a variable over time are a common focus of study in the social sciences. Traditional parametric models restrict such analyses to conditional MEANS and VARIANCES, leaving much of the distributional information untapped.

Relative distributional methods aim to move beyond means-based comparisons to conduct detailed analyses of distributional difference. As such, they present a general framework for comparative distributional analysis.

The relative DISTRIBUTION provides a graphical display that simplifies exploratory data analysis, a statistically valid basis for the development of hypothesis-driven summary measures, and location, shape, and covariate decompositions that identify the sources of distributional changes within and between groups.

The main idea of the relative distribution approach can be seen in an application to the comparison of earnings. The probability density functions (PDFs) in Figure 1(a) show the distribution of logged annual earnings for men and women who worked full-time, full-year in 1997. The women's distribution is clearly downshifted, but this graphical display provides little additional information useful for comparison.

The *relative distribution* is the set of percentile ranks that the observations from one distribution would have if they were placed in another distribution. In this example, it is the set of ranks that women earners would have if they were placed in the men's earnings distribution.

Figure 1(b) shows the density for the relative distribution of women's to men's earnings. The smooth line encodes the relative frequency of women to men at each level of the earnings scale; the value of this ratio is shown on the vertical axis. The top axis shows the dollar value of the log earnings, the bottom axis shows the rank in the men's distribution. The histogram encodes the fraction of women falling into each decile of the men's earnings distribution. We can see from the histogram that 20% of the women fall in the bottom decile of the men's earnings distribution, and another 18% in the second decile. In all, about 75% of women earn less than the median male (the sum of the first five deciles). By contrast, less than 5% of women's earnings reach the top decile of the men's distribution.

(a) Log Earnings PDFs for Men and Women, 1997

(b) Relative PDF, Women:Men

Figure 1

The differences between the men's and women's distributions can be divided into two basic components: differences in location and shape. If the women's earnings distribution is a simple downshifted version of the men's, then after matching the medians (or other location parameter), the two distributions should be the same. Differences that remain after a location adjustment are differences in distributional shape.

The relative distribution can be decomposed into these location and shape components, and Figure 2 shows the residual shape differences in men's and women's earnings. It is constructed by median-matching the women's earnings distribution to the men's (the median earnings ratio is about 1.4) and constructing the new relative distribution. After adjusting for median differences, the relative distribution is nearly flat, indicating that most of the difference between the two groups is due to the median downshift in women's earnings. There are some residual differences, however. Women's earnings have relatively less

Figure 2

density in the lower tail (because the bottom decile is below 1) and relatively more density in the upper tail. This probably reflects the dramatic losses experienced by low-earnings men in the past 20 years, and the corresponding gains made by high-earnings women. The lower tail difference may also signal a minimum wage effect, as the women's median is lower to begin with, so their lowest earnings are closer to their own median than is the case for men. More information on these trends can be found in the review article of Morris and Western (1999). Handcock and Morris (1999) is a book-length treatment of relative distribution theory and includes historical references.

RELATIVE FREQUENCY

One of the two primary reasons for applying statistical methods is to summarize and describe DATA. (The other reason is to make INFERENCES from the data.) *Relative frequency* is a simple tool to summarize

Table 1 Relative Frequency of Intelligence Quotient (Grouped Into Intervals of Five Units)

<i>Intelligence Quotient</i>	<i>Frequency</i>	<i>Relative Frequency</i>	<i>Percentage</i>
81–85	1	0.01	1.0
86–90	1	0.01	1.0
91–95	9	0.09	9.0
96–100	14	0.14	14.0
101–105	12	0.12	12.0
106–110	11	0.11	11.0
111–115	39	0.39	39.0
116–120	7	0.07	7.0
121–125	1	0.01	1.0
126–130	1	0.01	1.0
131–135	3	0.03	3.0
136–140	1	0.01	1.0
Total	100	1.00	100.0

Table 2 Relative Frequency of Occupational Attainment

<i>Occupation</i>	<i>Frequency</i>	<i>Relative Frequency</i>	<i>Percentage</i>
Professional	33	0.33	33.0
Blue-collar	21	0.21	21.0
Craft	25	0.25	25.0
White-collar	12	0.12	12.0
Menial	9	0.09	9.0
Total	100	1.00	100.0

complicated data by obtaining the *proportion* of observations that fall in an interval (for QUANTITATIVE VARIABLES) or belong to a specific category (for CATEGORICAL variables).

The relative frequency for an interval (or a category) equals the number of observations in that interval (or category) divided by the total number of observations. A listing of intervals or categories and their relative frequencies is called a *relative frequency distribution*. Presenting the relative frequency distribution of a variable gives an overall picture of the distribution of data *if* the way in which data are grouped into different categories or intervals is appropriate. Table 1 is an example of a relative frequency distribution for a quantitative variable, intelligence quotient (IQ). Table 2 is an example of a relative frequency distribution for a QUALITATIVE VARIABLE, occupational attainment.

The relative frequency for the first interval in Table 1 is $1/100 = .01$. That is, one person out of 100 people,

for a relative frequency of .01, has an IQ score between 81 and 85. Note that this hypothetical distribution arranges data into mutually exclusive intervals of five units. Likewise, the relative frequency for the first category in Table 2 is $33/100 = 0.33$. It might be interpreted as “33 people out of 100 people, for a relative frequency of 0.33, work in professional positions.”

Data analysts often report the percentage for an interval or a category instead of a relative frequency. The percentage for an interval or category is simply a relative frequency multiplied by 100. The far right column of both Table 1 and Table 2 reports the percentage for each classification or grouped interval. The total sum of relative frequencies should equal 1 because the frequencies are proportions. It is also clear that the total sum of percentages should equal 100. However, at times, the rounding process may lead to slightly different total sums, such as 0.998 (for relative frequency) or 100.01 (for percentage).

Note that the use of relative frequency or percentage implies considerable stability in data. Thus, if the total number of cases is fairly small, say, 15, then one should be cautious about using the relative frequency distribution. Hubert M. Blalock (1979) suggests two rules of thumb: (a) Always report the number of observations (i.e., frequency) along with relative frequencies and percentages, and (b) do not report a percentage or a relative frequency unless the total number of observations is in the neighborhood of 50 or more.

It is also noteworthy that the width of an interval for grouping quantitative data has a critical impact on how a relative frequency distribution will look. For example, regrouping data into intervals of 25 units for Table 1 may substantially change the shape of the relative frequency distribution and provides less information than the original Table 1.

However, there is no fixed answer for a question like, “Shall I use an interval of narrow width to get more detail, or shall I use a large interval size to get more condensation of the data?” It usually depends on the nature of the data and the purpose of the research. A convention is that 10 to 20 intervals give a good balance between condensation and detail. More information on reporting relative frequency may be available in Hays (1994) and Johnson and Bhattacharyya (2001).

Finally, data analysts can further use a HISTOGRAM to present graphically any sort of frequency distribution, regardless of the scale of measurement of the data. A histogram and its variants, such as BAR GRAPHS and PIE CHARTS, are useful ways to picture frequency

distributions. A good discussion of general principles for creating a histogram may be found in Cleveland (1993).

RELATIVE FREQUENCY DISTRIBUTION

A RELATIVE FREQUENCY distribution is one of several types of graphs used to describe a relatively large set of data. Examples are given in Figures 1 and 2. The first is for a quantitative variable, height in inches of males in the age range 20–25. The second is for course grades represented by the letters A–F, as commonly used in the U.S. system. These graphs are referred to as “relative” frequency distributions because the y-axis is a proportion scale, not a frequency scale. If 20 of 200 students are in the grade class “A,” then the relative frequency of this class is .10.

To create these graphs, one begins by grouping the full set of data into intervals or classes. The intervals or classes are plotted on the *x*-axis of a graph, using the midpoint of intervals or the label for classes. Bars (or columns) extend vertically above the *x*-axis to the point on the *y*-axis that represents the relative frequency of the interval or class.

Figure 1 A Distribution of Male Heights Displayed According to the Relative Frequency for Each 2-Inch Interval Between 52 and 82 Inches

Figure 2 The Distribution of Course Grades Displayed According to Their Relative Frequencies

Figure 3 A Cumulative Distribution of the Height Data in Figure 1; the y-Axis Values $\times 100$ Are Percentiles

A variation on the relative frequency distribution is to graph cumulative proportions. Using this method, proportions multiplied by 100 become percentiles. Figure 3 is a cumulative display of the height data in the relative frequency distribution for heights. Note that the x -axis values are the upper limits of intervals, not their midpoints as before.

—Kenneth O. McGraw

RELATIVE VARIATION (MEASURE OF)

The coefficient of relative variation (CRV) is the STANDARD DEVIATION of a variable normed by dividing by its MEAN. This measure is used to give a sense of how large the standard deviation is. Yule and Kendall (1968, pp. 143–144) consider it to be an absolute measure of

dispersion because the division by the mean controls for the variable's unit of measurement.

The formula for the coefficient of relative variation is $CRV = s/\bar{X}$, where s is the standard deviation of the variable and $\bar{X}$ is its mean (see also VARIATION, COEFFICIENT OF). The statistic is appropriate only for a ratio VARIABLE, because shifting the scale of an interval variable would change its mean and therefore the CRV. Division by values near zero produce very large values, so the coefficient of relative variation is considered unreliable when the mean is near zero. A variant of the formula is using the absolute value of the mean in the denominator, so that CRV is always positive. The relative variation of observation i can be defined as the DEVIATION of the i th value x_i on variable X from its mean, divided by the mean: $RV_i = (X_i - \bar{X})/\bar{X}$. The coefficient of relative variation is then equivalent to the square root of the average of the squared relative variations:

$$CRV = \sqrt{\frac{\sum (RV_i)^2}{N}}.$$

The coefficient of relative variation is useful in comparing the variation on variables with different mean values. For example, consider comparing the variances of crime rates across the months of a year in cities with very different average amounts of crime. There might be much greater variance in crime between months in New York City than in Peoria, simply because the crime rate is so much larger in New York City. Dividing the standard deviations by their respective means gives a normed result that better reflects whether crime rates really are more variable across the months of a year in New York City than in Peoria.

This coefficient is also useful for comparing the variation of variables measured in different units. For example, is there more variability to people's age or their number of years of education? There is generally greater variance on age than on education for adults, but that might not be the case when the standard deviations are normed by dividing through by their means. For example, if the mean age of a set of adults is 50 with a standard deviation of 20, the relative variation on age is 0.40. If their mean number of years of education is 12 years with a standard deviation of 6, the relative variation on education is 0.50 (see Table 1). There is greater variance on age than education in this example, but education actually has greater relative variation once the means are taken into account.

—Herbert F. Weisberg

Table 1 Hypothetical Age and Education Data

<i>Person</i>	<i>Age</i>	<i>Years of Education</i>
1	20	15
2	30	21
3	40	18
4	50	12
5	60	9
6	70	6
7	80	3
Mean	50	12
Standard Deviation	20	6
Coeff. Relative Variation	0.40	0.50

RELATIVISM

Relativism is a stance of systematic and thoroughgoing doubt about OBJECTIVIST, ESSENTIALIST, and foundational positions. It is not so much a position as an antiposition or a metaposition. Relativist arguments emphasize the inescapable role of RHETORIC in constructing claims as objective and foundational, as well as the contingency of tests, criteria, rules, experimentation, and other procedures that are claimed to guarantee objective foundations. Relativists do not deny the possibility of judgment (as is often claimed), but stress that judgment is bound up with broader human values, cultures, ways of life, and political visions in a way that cannot reduce to objective standards. Relativism is related to broader theoretical developments in social science; it can be seen as a philosophical correlate of POSTMODERNISM and constructionism, and the turn to discourse.

Relativism has been one of the most controversial, and often most despised, positions in social science. To say an approach or form of analysis has "slipped into relativism" was often considered sufficient to dismiss it. To be a relativist has been considered tantamount to endorsing (or at least not criticizing) the Holocaust or

spousal abuse, to be taking a position from which no judgment is possible and "anything goes."

Recently, debates about relativism often focus on the relation between REALISM and political or ethical critique. Some realists have argued that relativism fails to have sufficient purchase to develop political claims. Others have mobilized "death and furniture" arguments that highlight familiar and shocking atrocities (the massacre of the fleeing Iraqi army on the Basra road in 1991, female circumcision) or involve a sharp tap on an available table (Edwards, Ashmore, & Potter, 1995). Similar debates have emerged in feminism, where different ideas about gender and the nature of truth and politics have become contentious (Hepburn, 2000).

Richard Rorty (1991) has rethought issues in epistemology, ethics, and political philosophy along more relativist lines. He drew on Jacques Derrida's deconstructive philosophy to highlight the role of writing in constructing versions, making judgments, and constructing positions as apparently solid and timeless. His antifoundationalist arguments have considered the way judgments are grounded in claims that are themselves socially contingent. Barbara Herrnstein Smith (1997) argued that politics, morality, and cultural appraisal would be enriched rather than damaged by the relativist recognition of the failures of truth, rationality, and other notions central to objectivism.

Harry Collins (1985) has argued that methodological relativism is essential for a coherent study of scientific knowledge. He was a key figure in a sweep of new sociological work on science. This was distinct in not taking current scientific orthodoxy in any field as its start point, however plausible or established it might appear, because to do so would end up generating asymmetrical analyses (treating the orthodoxy as warranted by scientific observation, whereas the alternatives require social explanation). For example, in his research on gravitational radiation, Collins studied the rhetorical and persuasive work through which certain experiments were constructed as competent replications and certain claims were socially produced as incredible. Instead of starting with the then-conventional view that gravity waves had been found not to exist, he attempted to treat pro- and anti-gravity wave researchers in the same way. For this kind of analysis, instead of viewing scientific controversies as determined by a set of socially neutral rules and criteria that stand outside the controversy, criteria such as replication and testability become features of the controversy, with different scientists making different

judgments about what replication to trust and what test is definitive.

The centrality of relativism in the sociology of scientific knowledge is one of the reasons for its wider importance in contemporary social science. Building on this work, Malcolm Ashmore (1989) has developed a reflexive position that presses for an even more thoroughgoing relativism than Collins's. The need for methodological relativism in the sociology of scientific knowledge is now widely accepted. Jonathan Potter (1996) has argued that similar considerations are required when analyzing "factual accounts" in realms outside of science; otherwise, the same issues of taking sides and reinforcing the epistemic status quo will return.

Heated debate continues about moral and political consequences of relativist thinking.

—Jonathan Potter

RELIABILITY

Theories of reliability have been primarily developed in the context of psychology-related disciplines since Charles Spearman laid the foundation in 1904. Nevertheless, the emphasis on reliability in these areas does not imply that this issue is of little relevance to other disciplines. Reliability informs researchers

about the relative amount of random inconsistency or unsystematic fluctuation of individual responses on a measure. The reliability of a measure is a necessary piece of evidence to support the CONSTRUCT VALIDITY of the measure, although a reliable measure is not necessarily a valid measure. Hence, the reliability of any measure sets an upper limit on the construct validity.

An individual's response on a measure tends to unsystematically vary across circumstances. These unsystematic variations, referred to as RANDOM ERRORS or random errors of MEASUREMENT, create inconsistent responses by a respondent. Random errors of measurement result from a variety of factors that are unpredictable and do not possess systematic patterns. These factors include test-takers' psychological states and physiological conditions, characteristics of the test environments, different occasions of test administration, characteristics of the test administrators, or different samples of test items in which some are ambiguous or poorly worded. As a result, one or more of the above factors contributes to the unpredictable fluctuation of responses by a person should the individual be measured several times.

TYPES OF MEASUREMENT ERRORS

It is safe to say that most, if not all, measures are imperfect. According to a recent development in measurement theory, the scores for any measured variable likely consist of three distinguishable components: the construct of interest, constructs of disinterest, and random errors of measurement (Judd & McClelland, 1998). Of these, the latter two components are measurement errors, which are not desirable but are almost impossible to eliminate in practice. The part of the score that represents constructs of disinterest is considered SYSTEMATIC ERROR. This type of error produces orderly but irrelevant variations in respondents' scores. In contrast, a measure's random errors of measurement do not impose any regular pattern on respondents' scores. It should be noted that errors of measurement in a score are not necessarily a completely random event for an individual (e.g., Student Smith's test anxiety); however, across a very large number of respondents, the causes of errors of measurement likely vary randomly and act as RANDOM VARIABLES. Hence, errors of measurement are assumed to be random. It is the random errors of measurement that theories of reliability attempt to understand, quantify, and control.

EFFECTS OF RANDOM ERRORS ON A MEASURE

Inconsistent responses on measures have important implications for scientific inquiries as well as practical applications. Ghiselli, Campbell, and Zedeck (1981) pointed out that inconsistent responses toward a measure have little value if researchers plan to compare two or more individuals on the same measure, place a person in a group based on his or her ability, predict one's behavior, assess the effects of an intervention, or even develop theories. Suppose a university admissions officer wants to select one of two applicants based on an entrance examination. If applicants' responses on this test tend to fluctuate 20 points from one occasion to another, an actual 10-point difference between them may be attributed to errors of measurement. The conclusion that one applicant has a stronger potential to succeed in college than another could be misleading. Similarly, a decrease of 10 points on an anger measure after a person receives anger management treatment may result from unreliable responses on the measure. The amount of errors of measurement resulting from one or more factors can be gauged by a variety of reliability coefficients, which will be discussed in a later section.

CLASSICAL TRUE SCORE THEORY

There have been two major theories of reliability developed since 1904: classical true score theory, based on the model of parallel tests, and GENERALIZABILITY THEORY, based on the model of domain sampling. Historically, Spearman (1904, 1910) started to develop classical TRUE SCORE theory, and it was further elaborated on by Thurstone (1931), Gulliksen (1950), and Guilford (1954). Generalizability theory is a newer theory, proposed by Jackson (1939) and Tryon (1957), and later advanced by Lord and Novick (1969) as well as Cronbach and his colleagues (1972). Conventional reliability coefficients such as parallel-forms and alternate-forms reliability, TEST-RETEST RELIABILITY, INTERNAL consistency RELIABILITY, SPLIT-HALF RELIABILITY, INTERRATER RELIABILITY, and INTRA-CODER RELIABILITY are estimated based on classical true score theory, although these coefficients can also be estimated by generalizability theory (see a demonstration in Judd & McClelland, 1998). Because generalizability theory and its applications are described elsewhere in the *Encyclopedia*, we will focus only on classical true score theory in the remaining section.

Classical true score theory is a simple, useful, and widely used theory to describe and quantify errors of measurement. In general, classical theory operates under the following assumptions:

1. $X_i = T + E_i$.
2. $E(X_i) = T$.
3. $F(X_1) = F(X_2) = F(X_3) = \dots = F(X_k)$.
4. $\rho_{X_1 X_2} = \rho_{X_1 X_3} = \rho_{X_1 X_k} = \dots = \rho_{X_{(k-1)} X_k}$.
5. $\rho_{X_1 Z} = \rho_{X_2 Z} = \rho_{X_3 Z} = \dots = \rho_{X_k Z}$.
6. $\rho_{E_1 E_2} = \rho_{E_1 E_3} = \rho_{E_1 E_k} = \dots = \rho_{E_{(k-1)} E_k} = 0$.
7. $\rho_{E_1 T} = \rho_{E_2 T} = \dots = \rho_{E_k T} = 0$.

Assumption 1, $X_i = T + E_i$, states that an observed score (or fallible score) of a test i (X_i), consists of two components: true score (T) and random errors of measurement, E_i . Errors of measurement, caused by a combination of factors described earlier, can be either positive or negative across different parallel tests (defined later), and therefore make the observed scores either higher or lower than the true score.

A true score on a test does not represent the true level of the characteristic that a person possesses. Instead, it represents the *consistent* response toward the test, resulting from a combination of factors. Note that different combinations of factors can lead to a variety of consistent responses. For instance, consistent responses on a measure of intelligence in an environment with humidity, noise, and frequent interruptions are different from those on the same measure under a cool, quiet, and controlled environment. The former consistent response represents the true score for intelligence under the *hardship* environment, whereas the latter response is the true score for intelligence under the *pleasant* condition.

Assumption 2, $E(X_i) = T$, states that the true score is the expected value (mean) of an individual's observed scores, should the person be tested over an infinite number of parallel tests. For instance, assuming an individual receives a large number of k parallel tests, the observed score of each test for this person can be expressed as

$$X_1 = T + E_1,$$

$$X_2 = T + E_2,$$

$$\vdots$$

$$X_k = T + E_k.$$

Because errors of measurement are either positive or negative, the sum of these errors in the long run is

zero, $E(E_i) = 0$. As a result, the expected value of observed scores equals the true score.

Assumptions 3 through 5 are about the characteristics of parallel tests, which have theoretical as well as practical implications. Assumption 3, $F(X_1) = F(X_2) = F(X_3) = \dots = F(X_k)$, states that distributions of observed scores across k parallel tests are identical for a large population of examinees. According to the assumption of identical distributions, we expect $T_1 = T_2 = \dots = T_k$ and $\sigma_{X_1}^2 = \sigma_{X_2}^2 = \dots = \sigma_{X_k}^2$. In addition, CORRELATIONS among observed scores of the k parallel tests are the same, which is expressed as $\rho_{X_1X_2} = \rho_{X_1X_3} = \rho_{X_1X_k} = \dots = \rho_{X_{(k-1)}X_k}$ (Assumption 4). Finally, Assumption 5, $\rho_{X_1Z} = \rho_{X_2Z} = \rho_{X_3Z} = \dots = \rho_{X_kZ}$, states that there are equal correlations between observed scores and any other measure (Z), which is different from k parallel tests.

Assumptions 6 and 7 essentially state that errors of measurement are completely random. Consequently, correlations among errors of measurement across k parallel tests in a large POPULATION of examinees equal zero, as do the correlations between errors of measurement and the true score. Based on Assumption 7, a VARIANCE relationship among σ_X^2 , σ_T^2 , and σ_E^2 can further be expressed by $\sigma_X^2 = \sigma_T^2 + \sigma_E^2$. Specifically, the observed score variance in a population of examinees equals the sum of the true score variance and the errors of measurement variance. Deduced from the above relationship in conjunction with Assumption 3, errors of measurement variances across k parallel tests are equal to one another, $\sigma_{E_1}^2 = \sigma_{E_2}^2 = \dots = \sigma_{E_k}^2$.

THEORETICAL DEFINITION OF RELIABILITY

According to the variance relationship $\sigma_X^2 = \sigma_T^2 + \sigma_E^2$, a perfectly reliable measure occurs only when random errors do not exist (i.e., $\sigma_E^2 = 0$ or $\sigma_X^2 = \sigma_T^2$). When σ_E^2 increases, observed differences on a measure reflect both true score differences among the respondents and random errors. When $\sigma_X^2 = \sigma_E^2$, all of the observed differences reflect only random errors of measurement, which suggests that responses toward the measure are completely random and unreliable.

If we divide σ_X^2 on both sides of the above equation, the variance relationship can be modified as

$$1 = \frac{\sigma_T^2}{\sigma_X^2} + \frac{\sigma_E^2}{\sigma_X^2}.$$

Reliability of a measure is defined as

$$\frac{\sigma_T^2}{\sigma_X^2},$$

which can be interpreted as the squared correlation between observed and true scores (ρ_{XT}^2). Conceptually, reliability is interpreted as the proportion of the observed score variance that is explained or accounted for by the true score variance. Following the above assumptions, it further proves that a correlation between two parallel tests equals

$$\frac{\sigma_T^2}{\sigma_X^2}.$$

That is,

$$\rho_{X_1X_2} = \frac{\sigma_{T_1}^2}{\sigma_{X_1}^2} = \frac{\sigma_{T_2}^2}{\sigma_{X_2}^2}.$$

If a correlation between two parallel tests is 0.80, it suggests that 80% (not 64%) of the observed score variance is accounted for by the true score variance. We will hereafter use the general notation, $\rho_{XX'}$ and $r_{XX'}$, to represent reliability for a population and a SAMPLE, respectively.

PROCEDURES TO ESTIMATE RELIABILITY

A variety of reliability coefficients are based on classical true score theory, such as test-retest reliability, internal consistency reliability, interrater reliability, or intracoder reliability, which are reviewed elsewhere in the *Encyclopedia*. We will focus on three additional reliability coefficients: alternate-forms reliability, reliability of difference scores, and reliability of composite scores.

An alternate-forms reliability coefficient, also referred to as coefficient of equivalence, is estimated by computing the correlation between the observed scores for two similar forms that have similar means, STANDARD DEVIATIONS, and correlations with other variables. Generally, a group of respondents receives two forms in a random order within a very short period of time, although the time period between administrations may be longer.

When conducting interventions or assessing psychological/biological development, researchers are often interested in any change in scores on the pre- and posttests. The difference between scores on the same or a comparable measure at two different times

is often referred to as a change score or difference score (denoted as D). The reliability of the difference scores in a sample can be estimated by

$$r_{DD'} = \frac{s_X^2 r_{XX'} + s_Y^2 r_{YY'} - 2s_X s_Y r_{XY}}{s_X^2 + s_Y^2 - 2s_X s_Y r_{XY}},$$

where s_X^2 and s_Y^2 are variances of the pre- and posttests, $r_{XX'}$ and $r_{YY'}$ are the reliabilities of the tests, and r_{XY} is the correlation between the tests. If the variances of both measures are the same, the above equation can be rewritten as

$$r_{DD'} = \frac{\frac{r_{XX'} + r_{YY'}}{2} - r_{XY}}{1 - r_{XY}}.$$

Given that $r_{XX'}$ and $r_{YY'}$ are constant, stronger r_{XY} results in weaker $r_{DD'}$. Furthermore, $r_{DD'}$ moves toward zero as r_{XY} approaches the average reliability of the measures. In reality, the size of r_{XY} is often strong because of two measures' similarity. As a result, difference scores tend to have low reliability, even when both measures are relatively reliable.

In contrast to difference scores, researchers sometimes need to utilize a composite score based on a linear combination of raw scores from k measures. For example, a personnel psychologist may select job applicants based on a composite score of an intelligence test, a psychomotor ability test, an interest inventory, and a personality measure. The reliability of this composite score (C) can be estimated by

$$r_{CC'} = 1 - \frac{\sum_{i=1}^k s_i^2 - \sum_{i=1}^k (r_{ii'} s_i^2)}{s_C^2},$$

where s_C^2 and s_i^2 are variances of the composite score, and $r_{ii'}$ is the reliability of measure i . In practice, researchers may create the composite score based on a linear combination of STANDARDIZED SCORES from k measures. The reliability can be estimated by the simplified formula,

$$r_{CC'} = 1 - \frac{k - k\bar{r}_{XX'}}{k + (k^2 - k)\bar{r}_{XY}},$$

where $\bar{r}_{XX'}$ is the average reliability across k measures, and $\bar{r}_{XY}$ is the average intercorrelation among the tests. Assuming the average intercorrelation is constant, the reliability of the composite score is greater than the average reliability of the measures. Hence, the reliability of a composite score tends to be relatively more reliable.

STANDARD ERRORS OF MEASUREMENT

As noted earlier, reliability coefficients only inform about the *relative* amount of random inconsistency of individuals' responses on a measure. A test with a Cronbach's alpha of .90 suggests that the test is more internally consistent than another test with a Cronbach's alpha of .70. However, both reliability estimates do not provide *absolute* indications regarding the precision of the test scores. For instance, the Stanford-Binet Intelligence Scale is a very reliable measure with an internal consistency reliability of .95 to .99. Although the test is highly reliable, we are not confident in saying that a score of 60 is truly higher than the average of 50 by 10 points. More realistically, the 10 points reflect the true difference in intelligence *and* random errors of measurement.

In order to interpret test scores accurately, researchers need to take unreliability into consideration, which is gauged by the square root of the errors of measurement variance, or standard error of measurement (σ_E). Standard error of measurement, derived from

$$1 = \frac{\sigma_T^2}{\sigma_X^2} + \frac{\sigma_E^2}{\sigma_X^2},$$

is expressed as $\sigma_E = \sigma_X \sqrt{1 - \rho_{XX'}}$ in a population, which can be estimated by $\hat{\sigma}_E = s_E = s_X \sqrt{1 - r_{XX'}}$ from a sample. Conceptually, the standard error of measurement reveals how much a test score is expected to vary given the amount of error of measurement for the test. When σ_E is available, researchers can use it to form CONFIDENCE INTERVALS of the observed scores. Specifically, the observed score (X) in a sample has approximately 68%, 95%, and 99% confidence to fall in the range of $X \pm 1\hat{\sigma}_E$, $X \pm 2\hat{\sigma}_E$, and $X \pm 3\hat{\sigma}_E$, respectively.

FACTORS THAT AFFECT RELIABILITY ESTIMATES

While estimating the reliability of a measure, researchers cannot separate the respondents' characteristics from the measure's characteristics. For instance, test performance on an algebra test in part depends on whether the test items are difficult or easy. At the same time, a determination of the test items as easy or difficult relies on the ability of the test taker (e.g., college student vs. junior high school student; homogeneous group vs. heterogeneous group). When a group is so homogeneous that members

possess similar or the same algebraic ability, the variance of the observed scores could be restricted, which leads to a very low reliability even though the test could be perfectly reliable. The above examples clearly demonstrate that reliability estimates based on classical true score theory change contingent upon the group of test takers and/or the test items. Specifically, traditional procedures to estimate reliability are group dependent and test dependent, which suggests that the standard error of measurement (and reliability) of a measure is not the same for all levels of respondents. Empirical evidence has shown that the standard error of measurement tends to be smaller for the extreme scores than the moderate scores.

There are other characteristics of measures that affect reliability. First, according to the Spearman-Brown Prophecy formula, the reliability of a measure tends to increase when the length of the measure increases, given that appropriate items are included. The Spearman-Brown Prophecy formula is defined as

$$\hat{\rho}_{XX'} = \frac{n \times \rho_{XX'}}{1 + (n - 1)\rho_{XX'}},$$

where n is the factor by which an original test is lengthened, and $\hat{\rho}_{XX'}$ and $\rho_{XX'}$ are reliability estimates for the lengthened test and the original test, respectively. Second, empirical findings have shown that reliability coefficients tend to increase when response categories of a measure increase. A MONTE CARLO study has revealed that overall reliability estimates of a 10-item measure, such as test-retest reliability or CRONBACH'S ALPHA, increase when response categories increase from a 2-point scale to a 5-point scale. After that, the reliability estimates become stable. Test content can also affect reliability. For instance, the reliability of power tests can be artificially inflated if time limits are not long enough. Power tests refer to tests that examine respondents' knowledge of subject matter. When time limits are short, most respondents cannot answer all the items. As a result, their responses across items become artificially consistent.

Finally, reliability can be affected by the procedures researchers opt to use. As described earlier, reliability coefficients based on classical true score theory estimate one or two types of errors of measurement. For instance, internal consistency estimates response variations attributed to item heterogeneity or inconsistency of test content, whereas test-retest reliability estimates variations attributed to changes over time, including carry-over effects. In contrast, alternate-forms

reliability with a long lapse of time (e.g., 4 months) estimates two types of random errors, namely, those attributed to changes over time and inconsistency of test content. Although all reliability coefficients based on classical true score theory estimate the relative amount of errors of measurement, the errors estimated by different reliability coefficients are *qualitatively* different from each other. Hence, it is not logical to compare two different types of reliability estimates.

The fact that different random errors are being estimated by different reliability coefficients has an important implication when researchers *correct* for attenuation due to unreliability. Derived from the assumptions of classical true score theory, a population correlation between two true scores ($\rho_{T_X T_Y}$) can be adversely affected by unreliability of the measures (X and Y). The adverse effect can be deduced from the relationship between a population correlation and population reliabilities of measures X and Y ($\rho_{XX'}$ and $\rho_{YY'}$), which is defined as

$$\rho_{T_X T_Y} = \frac{\rho_{XY}}{\sqrt{\rho_{XX'} \rho_{YY'}}}.$$

Often, researchers want to show what the sample correlation ($\hat{r}_{XY}$) would be if both measures were perfectly reliable. Following the modified formula from above, the disattenuated correlation can be obtained by

$$\hat{r}_{XY} = \frac{r_{XY}}{\sqrt{r_{XX'} r_{YY'}}}.$$

The difference between $\hat{r}_{XY}$ and r_{XY} increases when one or both measures become less reliable. For instance, $\hat{r}_{XY}$ equals r_{XY} when $r_{XX'} = r_{YY'} = 1$. However, the size of $\hat{r}_{XY}$ becomes twice as much as r_{XY} when $r_{XX'} = r_{YY'} = 0.50$. In practice, the correction for attenuation tends to overestimate the actual correlation. Foremost, it does not seem tenable to assume that both $r_{XX'}$ and $r_{YY'}$ deal with the *same* type(s) of errors of measurement. Furthermore, there are many different types of errors of measurement that are not adequately estimated by classical true score theory. For instance, researchers may be interested in finding out how reliable an achievement test is when it is administered by both male and female administrators at two different times and at three different locations.

RELIABILITY AND VALIDITY IN QUALITATIVE RESEARCH

Among QUALITATIVE RESEARCHERS, the concepts of RELIABILITY and VALIDITY have eluded singular or fixed definitions. As the understanding of qualitative inquiry has evolved in varied ways, especially over the past 20 or so years, so have the understandings of both concepts.

RELIABILITY

In its original formulation among quantitative researchers, a study was considered reliable if it could be replicated by other researchers. Among qualitative researchers, there is a considerable division of thinking as to whether replication or the possibility of reproducing results has any import whatsoever in terms of judging the value of qualitative studies. Some people, such as Jerome Kirk and Marc Millar (1986), argue that reliability in the sense of repeatability of observations still has an important epistemic role to play in qualitative inquiry. They contend that for a study to be judged good or valid, the observations made in that study must be stable over time, and that different methods, such as interviews and observations, should yield similar results.

Others, most particularly Egon Guba and Yvonna Lincoln (1994), have noted that because of the philosophic assumptions underlying qualitative inquiry (e.g., reality is constructed), the concept of reliability should give way to the analog idea of dependability. They contend that replication is not possible for qualitative inquiry; all that can or should be expected from a researcher is a careful account of how she or he obtained and analyzed the data.

Finally, some now hold that there is little point in continuing to pose reliability as a criterion for judging the quality of studies. Although it is possible that one researcher in a particular setting may well repeat the observations and findings of another researcher in that setting, one should not be concerned if this does not happen. The basis for this claim derives from the realization that theory-free observation is impossible, or that researchers can observe the world only from a particular place in that world (Smith & Deemer, 2000). If this is so, then reliability can be given no special epistemic status and need not be an issue of consequence for qualitative researchers.

VALIDITY

For QUANTITATIVE RESEARCHERS, validity is a concept of major epistemic import. To say that a study is valid is to say that it is a good study in that the researcher has accurately represented the phenomena or reality under consideration. For various related reasons, most particularly the rejection of naive or direct REALISM and the rejection of an epistemological foundationism, qualitative researchers do not find this definition of validity acceptable. Qualitative researchers have replaced realism and foundationalism with a variety of positions ranging from indirect or subtle realism and epistemological quasifoundationalism (fallibilism) to nonrealism and nonfoundationalism with numerous variations on theme in between (Smith, 1993). Because of this situation, the efforts by qualitative researchers to replace the traditional understanding of validity has led to an almost bewildering array of definitions and variations on definitions for this concept.

Martyn Hammersley (1990) is representative of those who have advanced an understanding of validity based on a subtle or indirect realism, combined with a quasifoundationalism or fallibilist epistemology. For him, a judgment of validity is not a matter of the extent to which an account accurately reproduces reality, but rather a judgment about the extent to which an account is faithful to the particular situation under consideration. This means that even though we have no direct access to reality and our judgments are always fallible, there still can and must be good reasons offered for claiming an account as true. These considerations lead to a definition of a valid study as one whose results have met the tests of plausibility and credibility. The former is a matter of whether or not an account of a situation is likely true given the existing state of knowledge of that situation. The latter directs attention to whether or not

a researcher's judgment is accurate given the nature of the phenomena, the circumstances of the research, the characteristics of the researcher, and so on.

A second broad approach, which also is, to one degree or another, based on an indirect realism and a quasifoundationalism, involves a wide variety of what can be called "hyphenated" definitions of validity. Numerous terms, such as *catalytic*, *situated*, *voluptuous*, *transgressive*, *ironic*, and *interrogated*, have been placed as modifiers to the term *validity*. Both David Altheide and John Johnson (1994) and Patti Lather (1993) have discussed these and various other possibilities.

Finally, some qualitative researchers see little reason to bother with the concept of validity. Because these people have accepted nonrealism and nonfoundationalism, they see little point in continuing to talk about true accounts of the world or of accurate depictions of an independently existing reality. They claim that all that is available to us are different linguistically mediated social constructions of reality. As such, the most that can be said for validity is that it is a matter of social agreement, and such agreements are not epistemological, but rather political and moral ones (Schwandt, 1996; Smith & Deemer, 2000).

RELIABILITY COEFFICIENT

A reliability coefficient is a measure of the proportion of true variance relative to the total observed score variance resulting from the application of a measurement protocol (such as a test, a scale, an expert rating, etc.) to a population of individuals.

Any measurement operation of a given attribute provides an observed score for that attribute, which, in principle, may be broken down into a TRUE SCORE component plus a measurement error component. The true score is conceived as an unknown constant within each individual, whereas the error component is modeled as a random variable uncorrelated with both the true score and other error components. Based on these properties, it has been algebraically demonstrated that the squared correlation of *observed* and *true* scores for a given population equals the proportion of the *true score* variance relative to the *observed score* variance, which is a reliability coefficient (see RELIABILITY). Thus, for a perfectly reliable assessment, the observed score variance is entirely accounted for by the true variance, and the resulting coefficient is 1.00. Conversely, for a totally unreliable assessment, the observed score variance has nothing to do with actual differences in the attribute to be measured, and the resulting reliability coefficient is .00. Although no absolute standard for a reliability coefficient exists, .70 and .90 are considered as the minimum acceptable values of reliability for group comparison and for making individual decisions, respectively.

So far, we defined a reliability coefficient in terms of observed score and true score variability. However, whereas the observed score is available after any measurement operation, the true score is, by definition, impossible to get to directly. In spite of this, the reliability coefficient can be obtained indirectly by looking at the consistency of the observed scores across repeated measures. The most popular methods for examining score consistency are (a) TEST-RETEST RELIABILITY, (b) alternate-form (or equivalent-form) reliability, (c) SPLIT-HALF RELIABILITY, and (d) CRONBACH'S ALPHA coefficient.

Methods (a) and (b) address the question of whether a test, or statistically equivalent parallel forms of a test, given twice to the same individuals, would provide the same set of observed scores on each occasion. Methods (c) and (d) address the question of whether statistically equivalent parallel empirical indicators used to

measure a single theoretical concept would correlate with each other on a single occasion.

Some research designs involve behavior rating by experts according to a predefined scale or coding procedure. INTERRATER RELIABILITY and intrarater reliability coefficients represent additional types of reliability coefficients that apply to these measurement protocols.

Once the reliability coefficient has been evaluated by any of the above methods, one can use it to compute the standard error of measurement, which can be used to estimate—punctually or from a CONFIDENCE INTERVAL—one's true score by one's observed score.

Factors influencing the reliability coefficient are test length (i.e., tests comprised of more items provide higher reliability coefficients), examinee heterogeneity (i.e., reliability increases as individual differences in the attribute to be measured increase), and test difficulty (i.e., a moderately difficult test increases the likelihood of detecting individual differences).

REPEATED MEASURES

The term *repeated measures* refers to how the design for the data collection is such that data are collected more than once on each unit. The unit may be a child, with the pediatrician measuring the weight of the child at yearly intervals; a country, with measures of inflation over several years; or a couple, with incomes for husband and wife. Repeated measures often involve data collected over time. The problem now is that there is no independence between the observations for a unit the way there is when there is only one observation on each of many units.

Repeated measures can involve data collected only twice. This is the paired data design, and it leads to the *T-TEST* for paired data. Husband-wife income data are of this kind, as are experimental data with a before-after design. It is tempting to simply do a

t-test for the difference between two gender means, but that does not take into account the paired nature of the data. The numerators for the *t*-test for the difference between two means and the paired *t*-test are identical, and equal to the difference between the means for the two groups. The difference is in the denominators. Suppose one couple has high incomes and another couple has low incomes. This variation is included in the STANDARD DEVIATION and therefore increases the denominator in the test for two means, making for a smaller value of *t* and therefore a larger *P* VALUE. In the paired test, what matters are the *differences* between husbands' and wives' incomes, and it does not take into account whether the original values are high or low. By eliminating this source of variation, the denominator becomes smaller, the *t* value becomes larger, and the corresponding *p* value becomes smaller and more significant. The only adjustment is in the DEGREES OF FREEDOM. The test for the difference of two means has $n_1 + n_2 - 2$ degrees of freedom, whereas the paired test has only $n - 1$ degrees of freedom.

The paired *t*-test is equivalent to a two-way ANALYSIS OF VARIANCE, with one observation in each cell and the interaction mean square used in the denominator for the *F*s instead of the residual mean square. One factor is gender, with 2 values, and the other factor is couple, with *n* values. Now we get the effect of gender after taking out the effect of couple. Numerically, *F* on 1 and $n - 1$ degrees of freedom for gender from the analysis of variance equals t^2 from the paired *t*-test.

If there is a factor with more than two categories, the paired *t*-test *generalizes* to a two-way analysis of variance with one observation in each cell, and the interaction mean square is used in the denominator for *F*. In this case, there is no corresponding *t*-test. Repeated measures analysis becomes TIME-SERIES analysis when the observations are made at known points in time on only one unit.

REPERTORY GRID TECHNIQUE

Derived from Kelly's personal construct psychology (see Fransella & Bannister, 1977), repertory grid technique is a method for representing and exploring a person's understanding of things. It is particularly useful for getting people to articulate their knowledge of topics to which they have previously given little thought, or find difficulty expressing. A simplified grid is shown in Table 1. It comprises four features:

- *A Focus.* In Table 1, the focus is the skills of team members in a manufacturing organization.
- *Elements.* These are the objects of thought. Elements are often people but can be places, ideas, or inanimate things.
- *Constructs.* These are the qualities the person uses to describe and differentiate between the elements. Constructs are bipolar and have positive and negative ends.
- *A Linking Mechanism.* This refers to how the elements are related to the constructs. It can be a categorical, binary, or continuous scale.

A common way of completing a grid is for the researcher to supply its focus. The participant is then asked to select examples of elements, for example, a skilled team member you know. Constructs are then

generated by "triading"—selecting three elements and stating how two are similar to, but different from, a third. The positive and negative sides of each construct are specified. Triading is repeated until no more constructs can be generated. The person then links the constructs to elements by scoring their relationship. Variations in grid completion include generating constructs by simply comparing and contrasting two elements (dyading), and supplying the elements and/or constructs. Some see supplying elements or constructs as counter to the aim of grids (i.e., to explore "personal" understanding).

Grids are analyzed by examining the meaning of constructs, as well as the relationships between constructs (e.g., do constructs cluster to form a superordinate factor?), between elements, and between constructs and elements (e.g., which constructs associate with which elements?). Qualitative and quantitative analytical procedures can be used separately or, preferably, in combination. The complexity of the grid means that quantitative techniques are particularly useful (see Leach, Freshwater, Aldridge, & Sunderland, 2001, for an overview). However, some argue that quantitative analysis detracts from or violates the interpretivist assumptions that underlie repertory grids, whereas others state that it can ignore the rich data generated from the interview itself. Qualitative analysis of construct meanings and the interview is therefore recommended.

Table 1 A Simplified Repertory Grid Showing a Manufacturing Manager's Understanding of His Team Members' Skills

Constructs (Positive Pole)	Elements						Constructs (Negative Pole)
	Skilled Operator	Skilled Operator	Averagely Skilled Operator	Averagely Skilled Operator	Unskilled Operator	Unskilled Operator	
	Leslie	Ann	Frank	Denise	Julie	David	
Time keeping	✓	✓	✓	×	✓	✓	Poor time keeping

Quality awareness	×	×	✓	✓	×	×	Lacks awareness
Appropriate communication with manager	✓	✓	×	✓	×	×	Poor communication
Suggests ideas	✓	✓	✓	×	×	×	Doesn't want to improve performance
Competitive	✓	×	×	×	×	×	Uncompetitive
Solves problems on own	✓	✓	✓	✓	×	×	Always seeks help

SOURCE: Adapted from Easterby-Smith, Thorpe, and Holman (1996).

Finally, there are a number of limitations to the use of grids. It is a time-consuming process for all involved. The interview process can bring up personal and sensitive issues, and the interviewer needs to be skilled in dealing with these. Unless change is a specific focus, repertory grid interviews are not adept at elucidating change processes (i.e., how and why things change).

REPLICATION

The purpose of a social science EXPERIMENT is to estimate (a) the effect of some treatment on certain output variables in members of a given POPULATION, (b) the difference(s) between two or more populations with respect to some variable(s), or (c) the relationship or CORRELATION between two or more variables within some specified population. All such experiments can lead to erroneous conclusions if the measures employed are invalid, if the samples are not representative of the specified populations, or if extraneous but unidentified factors influence the dependent variables. Therefore, before accepting the results of any such experiment as establishing an empirical fact, such experiments should be repeated or replicated.

The closest one might come to a *literal replication* might be for the original author to draw additional samples of the same size from the same populations, employing all the same techniques, measuring instruments, and methods of analysis as on the first occasion. The results of the original SIGNIFICANCE TESTING (e.g., “ $p \leq .01$ that Measures A and B are positively correlated in the population sampled”) predict the outcome of (only) a truly literal replication. That literal replications are seldom possible is no great loss inasmuch as they may succeed, not only if the original finding was

valid, but also if the finding was invalid but the author was consistent in making the same crucial mistakes.

Operational replication occurs when a new investigator repeats the first study, following as closely as possible the “experimental recipe” provided by the first author in the Methods section of his or her report. A successful operational replication provides some assurance that the first author’s findings were not the result of some unknown and uncontrolled variables.

A limitation of operational replication is that its success does not necessarily support the claim that, for example, “Constructs X and Y are positively correlated in Population Z,” but only that “Scores obtained using Measures A and B are positively correlated in samples drawn in a certain way from Population Z.” Those scores may not be good measures of the constructs, and/or the sampling methods may not produce samples representative of Population Z. Moreover, neither authors nor editors of the psychological literature have learned to limit the Methods sections of research reports to contain all of, and only, those procedural details that the first author considers to have been necessary and sufficient to yield the findings obtained.

The most risky but most valuable form of replication is *constructive replication*, in which the second author ignores everything in the first report except the specific empirical fact or facts claimed to have been demonstrated. The replicator chooses methods of sampling, measurement, and data analysis that he or she considers to be appropriate to the problem.

An experiment that claims to have confirmed a theoretical prediction can be usefully replicated in two ways: The validity of the prediction can be constructively replicated, or the incremental validity of the theory can be constructively replicated by experimentally testing new and independent predictions that follow from the theory. Thus, Lykken (1957, 1995) tested three predictions from the theory that the primary psychopath starts life at the low end of the BELL-SHAPED CURVE of genetic fearfulness. Several investigators constructively replicated the original findings, whereas Hare (1966), Patrick (1994), and others have experimentally confirmed new predictions from the same theory.

REPLICATION/REPLICABILITY IN QUALITATIVE RESEARCH

This concept shares much with that of RELIABILITY in that both refer to the extent to which a research operation is consistently repeatable. If consistency between researchers is achieved, more faith is placed in the truth of the findings. REPLICATION refers to the extent to which a re-study repeats the findings of an initial study. Replicability is the extent to which such re-study is made feasible by the provision of sufficient information about research procedures in the first study.

These ideas depend on philosophical assumptions that are not shared by all QUALITATIVE RESEARCHERS. For example, researchers committed to an idealist vision of the way in which language constructs versions of reality often regard their own texts (research reports, etc.) as constructing their objects of study, rather than reporting truths in conventional realist fashion. If this relativist, social constructionist view is taken, it makes little sense to seek out replication, as each account is simply one more “partial truth” (Clifford & Marcus, 1986).

Where realist assumptions are made, replication in qualitative research is not without difficulties either. Erasure of the personal idiosyncracies of the researcher is fundamental to the natural scientific worldview and to some versions of quantitative social research, but this is well-nigh impossible in qualitative research. In fieldwork, a great deal of what emerges depends on the personal attributes, analytic insights, and social skills of the researcher, and these are unlikely to be shared fully by any second researcher. Much of the strength of qualitative research lies in in-depth examination of particular cases, seen in the richness of their (sometimes unique) contexts. Cases do not remain static over time and may not share very much with other cases that, at some other level, are judged to be the same. Observers looking at the “same” case at some later time, or attempting to study “similar” cases, may, in effect, be studying different things, and they

do so using different instruments (i.e., themselves). Attempts at replicating some of the more famous studies in qualitative social research (Mead and Freeman in Samoa; Lewis and Redfield in Mexico; Whyte and Boelen in Boston—summarized in Seale, 1999) have encountered these problems, and in retrospect, these attempts (and the embarrassment they provoked in their respective disciplines) appear naïve.

Replicability, however, is a more realistic goal, although perhaps it should be renamed “methodological accounting” in view of the practical difficulties reviewed. The documentation of research procedures, as well as reflection on the influence on a research project of prior assumptions and personal preferences, can help readers assess the adequacy with which researchers’ claims have been supported. Lincoln and Guba (1985) have outlined a scheme for AUDITING a research project, in which such documents and reflections are investigated by a team of research colleagues toward the end of a research project in order to assess methodological adequacy. Although such elaborate and expensive exercises are rarely carried out, in general, there has been a turn toward methodological accounting in qualitative research reports, and this is perhaps as far as is practical to go in the direction of the full experimental replications demanded by natural scientists as a matter of course.

REPRESENTATION, CRISIS OF

The phrase *crisis of representation* refers to the claim that social researchers are unable to directly represent or depict the LIVED EXPERIENCES of the people they study. The implications of this claim are twofold. First, the phrase announces that the core ideas that had long dominated the understanding of researchers about the nature of social research are no longer viable. The classic norms of OBJECTIVITY, VALIDITY, truth as

correspondence, and so on are no longer applicable to our understanding of inquiry. Second, in response to the demise of these ideas, there is the further understanding that the lived experiences of people are not discovered by researchers to be depicted as they really are; rather, these experiences are constructed by researchers in their interpretations of the interpretations of others as presented in their written social texts. The implications of this shift from discovery or finding to constructing or making are still being worked out.

The phrase was, if not coined, certainly brought to the attention of many social researchers by George Marcus and Michael Fischer in 1986. However, prior to that, the idea that the direct or objective representation of the experiences of people by researchers was an impossibility had been intellectually fermenting over the course of the 20th century and even earlier. Tracings of this concern can be found, for example, in the late 19th- and early 20th-century antipositivist writings of various German scholars, in the realization at midcentury by many philosophers of science that there can be no possibility of theory-free observation, and in the acknowledgment in the 1970s and early 1980s that anthropological writings are interpretations of interpretations and that the boundaries of social science and the humanities had become blurred (Smith, 1989).

Today, the crisis of representation as a "crisis" has more historical than contemporary interest. Although there is still a problem of representing others or speaking for others that researchers must address, the sense of crisis has diminished. The reason for this is that the ideas that objectivity is not possible, that correspondence is not an adequate theory of truth, that there is no theory-free knowledge, and so on, have become widely accepted by social researchers. Accordingly, the task now is to elaborate on and explore the implications of these realizations. It is in this sense that Norman K. Denzin and Yvonna S. Lincoln (2000) note that the crisis of representation, which marked the fourth moment of qualitative inquiry, has led to a fifth moment (the postmodern), a sixth moment (the postexperimental inquiry), and a now developing seventh moment focusing on inquiry as moral discourse.

REPRESENTATIVE SAMPLE

The purpose of a sample design is to select a subset of the elements or members of a POPULATION in a way that STATISTICS derived from the SAMPLE will represent the values that are present in the population. In order to have a representative sample, a PROBABILITY method of selection must be used, and every element in the population has to have a known, nonzero chance of selection. When such a method is employed well, then the researchers can be confident that the statistics derived from the sample apply to the population within a stated range and with a stated degree of confidence.

The relevant population is theoretically defined on the basis of a specific research HYPOTHESIS. It consists of a set of elements that comprises the entire population, such as "adults residing in the United States." The easiest way to draw a probability sample is to have a list of all of the elements in the population, called a SAMPLING FRAME, and then apply a probability design to the sampling frame to produce a representative sample.

For many sampling problems, a list of all of the elements in the population exists, or at least a very good approximation of it does. In order to estimate the proportion of drivers who had an accident in the past year, a researcher might want to interview drivers and ask them whether they had an accident in the preceding 12 months. In order to produce a sample of drivers, for example, a researcher could start with a list of all individuals with a driver's license. The list might actually include all of those with licenses as of a recent date, and the list would have to be updated to include those who had received licenses since that date.

In another instance, a researcher might be interested in estimating how many American adults have a credit card. There is no existing list of all adults in the United States, so it has to be developed or approximated in the course of the study itself. This is a typical problem for those who conduct TELEPHONE SURVEYS. In this case, it is common to use a MULTISTAGE SAMPLING process that begins with a sample of telephone numbers. This is commonly generated by a computer to account

for unlisted numbers and newly assigned ones. These numbers are called, and when a residence is contacted, all of the adults residing there are listed. Through this multistage process, a CLUSTER SAMPLING of adults residing in telephone households is produced; and in the final step, one is selected at random as the respondent. That person is asked whether he or she has a credit card.

The key question for the researcher is how well the sample estimate (proportion of drivers who had a traffic accident in the past year or proportion of adults who carry a credit card) represents the population value. This is a function of two properties of the sample: its CONFIDENCE INTERVAL and confidence level. The primary advantage of using a probability method is that it allows researchers to take advantage of the NORMAL DISTRIBUTION that results from drawing repeated samples with a given characteristic from the same population. The properties of this SAMPLING DISTRIBUTION include information about the relationship between the STANDARD DEVIATION of the distribution and the size of the samples, as well as the distribution of the resulting sample estimates.

Given these properties, if we estimated from interviews with a simple random sample of 1,000 drivers that 14% of them had an accident in the past year, we would be 95% confident that the “true value” in the total population of all drivers ranged between 11% and 17% (the 14% estimate $\pm$ the three-percentage-point margin of error). The application of the probability design to a good frame ensures that the result is a representative sample with known parameters that indicate its relative precision.

RESEARCH DESIGN

The logical structure of the data in a research project constitutes the project's research design. Its purpose is to yield empirical data that enable relatively unambiguous conclusions to be drawn from the data.

The purpose of a research design is to test and eliminate alternative explanations of results. For example,

research to test the proposition that marriage harms the mental health of women and benefits that of men requires careful attention to research design. One design could simply compare the incidence of depression among married women with that among married men. A finding that depression rates are higher among married women than married men is *consistent* with the proposition but does nothing to eliminate alternative explanations of this finding. If never-married women are also more depressed than never-married men, then the higher depression levels of married women (compared to married men) can hardly be attributed to marriage. Similarly, if the depression rates among women are lower after they marry than before, then the greater depression levels of married women (compared to married men) are not due to marriage.

A good research design will collect the type of data that tests each of these alternatives. The more alternative explanations that are empirically eliminated, the stronger the final conclusion will be.

Most social research designs rely on the logic of *comparing groups* (Stouffer, 1950). These comparisons strengthen tests of any proposition, test alternative explanations, and bear directly on the confidence in the conclusions and interpretations drawn from the data. For example, in the above example, three different comparisons are mentioned:

- Married men with married women
- Never-married men with never-married women
- Women before and after they marry

A design based just on the first comparison would yield weak and ambiguous conclusions open to a number of alternative explanations. If the design also included data based on the other comparison groups, less ambiguous conclusions could be drawn.

Research designs vary not just in terms of which comparisons are made, but also in the nature of the groups that are compared and in the way in which group members are recruited.

The four main types of research designs (de Vaus, 2001) used in social research are the following:

- Experimental
- Longitudinal
- Cross-sectional
- Case study

Although some writers use the term *research design* to describe the *steps* in a research project or even the method of collecting data (e.g., interview, observation,

etc.), this is misleading (Yin, 1989). Research design is not simply a research plan or a method of collecting information—design is a *logical* rather than a *logistical* exercise. It is analogous to the task of an architect designing a building rather than a project manager establishing a project management schedule.

All research, regardless of the method of data collection and irrespective of whether it has a QUANTITATIVE or a QUALITATIVE emphasis, has a research design. This design may be implicit or explicit. Where it is implicit, the design is often weak in that useful comparison groups are not built into the research, thus weakening the conclusions that can be drawn from the data.

RESEARCH HYPOTHESIS

Empirical research is done to learn about the world around us. It flows from general hunches and theories about behavior—social, biological, physical, and so on. Most research is concerned about possible relationships between variables, and hunches and theories get translated into specific statements about variables. Such statements become research hypotheses, stating how the researcher thinks the variables are related. Because it is not known whether these statements are true or not, they can be considered questions about the world. Hopefully, collecting and analyzing empirical data will provide answers.

“Do Republicans make more money than Democrats?” might be one such question as a part of a larger theory of political behavior, and a possible research hypothesis is, “Republicans make more money than Democrats.” Data can be obtained in a SAMPLE survey about how people voted and on their annual incomes.

A research hypothesis must first be translated to a statistical NULL HYPOTHESIS. The machinery of statistical inference does not make use of the research

hypothesis directly. Instead, one or more statistical parameter are identified, and possible values of the PARAMETERS are stated in such a way that they replace the research hypothesis. This produces a statistical NULL HYPOTHESIS, which then can be analyzed using methods of statistical inference, using classical statistical HYPOTHESIS TESTING. A BAYESIAN approach would avoid some of the difficulties associated with the frequentist hypothesis testing.

The translation from the research hypothesis to a more specific statistical null hypothesis can be difficult. For our example, one possible null hypothesis is that the mean population income for Republicans is equal to the mean population income for Democrats ($H_0 : \mu_r = \mu_d$). That way, the original question is shifted to a question about means, which may or may not be what the researcher has in mind.

Also, the statistical null hypothesis states that the means are equal for the two groups, whereas the research hypothesis states that one group is higher, in some way, than the other group. The focus here is on the term *equal*, even though the research hypothesis is framed in terms of *larger*. The reason for this is that the aim of most research is to prove the null hypothesis of no difference or no relationship to be wrong. If we can eliminate the possibilities that two means are equal, then we have shown that they must be different. This becomes a double-negative way of proving a research hypothesis to be true.

Even if the data show a research hypothesis to be true, the data deal only with statistical associations or differences and not CAUSAL patterns in the variables. Causality is hard to establish, and most often it is limited to data obtained from experiments. Observational data do not lend themselves easily to determining causality. One of the very few cases of causality established from observational data is the one stated on every pack of cigarettes: Smoking is bad for your health.

RESEARCH MANAGEMENT

There are many aspects to the successful management of a research study or a research organization. Essentially, the primary goal of a research manager is to utilize available resources to best maximize the quality (i.e., RELIABILITY and VALIDITY) of the data gathered for a study or by an organization. This is neither an easy nor a straightforward process, and those who hold positions in research management will benefit from being experienced researchers in their own right. Ultimately, researcher managers must be able to aid wise decision making about the many design and operational trade-offs that are faced in planning and implementing any research study. That is, there are only finite resources available for any study, and these must be deployed wisely (from a cost-benefit standpoint).

In addition to having experience and expertise in the methodological and statistical aspects of the research that will be conducted, a successful manager or management team is likely to need knowledge and skills in fund-raising, finance, personnel management, communication and public relations, and research ethics. Without adequate financial and personnel resources, a research study will not be able to gather DATA of a level of quality that is adequate for the goal(s) of the research. Therefore, skills in fund-raising are needed to attract the resources necessary to collect valid data and to adequately analyze, interpret, and disseminate the findings. A manager also is responsible for seeing that competent staff are recruited, hired, motivated, evaluated, and retained in order to sustain the necessary work. Communication skills are needed so that the new knowledge generated by the research can be adequately disseminated. (In many instances, dissemination helps the cause of future fund-raising.) Management also must have a careful eye to all the ethical aspects of the research, especially as they relate to protecting the well-being of any humans, other animals, and/or the environment that the research may affect and that an institution's Institutional Review Board processes must sanction.

—Paul J. Lavrakas

RESEARCH QUESTION

Research questions state a research problem in a form that can be investigated and define its nature and

scope. It is through the use of such questions that choices about the focus and direction of research can be made, its boundaries can be clearly delimited, manageability can be achieved, and a successful outcome can be anticipated. One or more research questions provide the foundation on which a research project is built. Their selection and wording determines what, and to some extent, how, the problem will be studied.

There are three main types of research questions: what, why, and how. “What” questions require a descriptive answer; they are directed toward discovering and describing the characteristics of and regularities in some social phenomenon (e.g., categories of individuals, social groups of all sizes, and social processes). “Why” questions ask for either the causes of, or the reasons for, the existence of characteristics or regularities. They are concerned with understanding or explaining the relationships between events, or within social activities and social processes. “How” questions are concerned with bringing about change, and with practical outcomes and intervention (Blaikie, 2000, pp. 60–62).

These three types of research questions form a sequence: “What” questions normally precede “why” questions, and “why” questions normally precede “how” questions. We need to know what is going on before we can explain it, and we need to know why something behaves the way it does before we can be confident about introducing an intervention to change it. However, most research projects will include only one or two types of research questions—most commonly, “what” and “why” questions—and some research may deal only with “what” questions (Blaikie, 2000, pp. 61–62).

Some writers have proposed more than three types of research questions, such as “who,” “what,” “where,” “how many,” “how much,” “how,” and “why” (e.g., see Yin, 1989). However, all but genuine “why” and “how” can be transposed into “what” questions: “what individuals” in “what places,” at “what time,” in “what numbers or quantities,” and in “what ways.”

Research projects differ in the extent to which it is possible to produce precise research questions at the outset. It may be necessary to first undertake some exploratory research. In addition, what is discovered in the process of undertaking the research is likely to require a review of the research questions from time to time.

Formulating research questions is the most critical and, perhaps, the most difficult part of any RESEARCH DESIGN. However, few textbooks on research methods

give much attention to them, and some ignore this vital part of the research process entirely; those that do discuss them tend to focus on qualitative research (e.g., see Flick, 1998, and Mason, 2002).

Conventional wisdom suggests that research should be guided by one or more hypotheses. Advocates of this position suggest that research starts with the formulation of the problem, and that this is followed by the specification of one or more hypotheses, the measurement of concepts, and the analysis of the resulting variables to test the hypotheses. However, this procedure is relevant only in quantitative research that uses DEDUCTIVE logic. Although there is an important role for hypotheses in this kind of research, they do not provide the foundation for a research design, nor are they very useful for defining its focus and direction.

In some kinds of research, it is impossible or unnecessary to set out with hypotheses. What is required is the establishment of one or more research questions. The role of hypotheses is to provide tentative answers to “why” and, sometimes, “how” research questions. They are our best guesses at the answers. However, they are not appropriate for “what” questions. There is little point in hazarding guesses at a possible state of affairs. Research will produce an answer to a “what” question in due course, and no amount of guessing about what will be found is of any assistance (Blaikie, 2000, pp. 69–70).

RESIDUAL

Residuals measure the distance between the actual and predicted values for any estimator. If $\hat{y}$ (read y hat) is the estimated value of y , then the residual ($\hat{u}$) can be calculated by simply subtracting the true value of y from the estimated value: $\hat{u} = \hat{y} - y$. Residuals are used in a variety of ways. They are used to calculate REGRESSION lines, assess GOODNESS-OF-FIT MEASURES, and as a diagnostic in data analysis.

ORDINARY LEAST SQUARES (OLS) uses squared residuals to produce regression estimations. OLS fits a regression line to the data so the square of the residuals is minimized. Thus, OLS produces a regression line with the smallest residuals possible. The normal equations carried out by OLS produce residuals with certain properties. First, the expected values of the residuals are equal to zero. This does not mean all the residuals are equal to zero, but rather, the average of all residuals equals zero. Second, the sample COVARIANCE between each INDEPENDENT VARIABLE and the OLS residual is zero. Additionally, the sample covariance between the OLS residual and the fitted values is zero (Wooldridge, 2003).

Residuals are also used in assessing the goodness of fit of the regression model. We assess goodness of fit by how close the actual values are to the estimated regression line; the closer the values, the better the fit. Residuals are used in computing several different measures of goodness of fit. *R-SQUARED* and *ROOT MEAN SQUARE error* (root MSE) are two different measures of goodness of fit that employ residuals in their calculations.

Residuals also can tell us a considerable amount about our DATA and MODELS. Many times in the data analysis process, we examine the residuals. This can be done by looking at them in relation to the plotted regression line. If the residual is negative, we know that the regression equation overpredicts the value of the DEPENDENT VARIABLE. If the residual is positive, the regression line underpredicts the value of the dependent variable. Examining the residuals in this manner can tell us if there are certain types of observations where our model performs poorly. Damodar N. Gujarati (2003) suggests that plotting residuals is a useful exercise. In CROSS-SECTIONAL DATA, plotting the residuals can reveal problems with model MISSPECIFICATION and HETEROSKEDASTICITY. If a model lacks an important variable, or if the wrong functional form is specified, the residuals will form distinct patterns. In TIME SERIES, examining the residuals is a useful exercise for detecting heteroskedasticity and AUTOCORRELATION.

RESIDUAL SUM OF SQUARES

One of the key components of ANALYSIS OF VARIANCE (ANOVA) and REGRESSION, both LINEAR and multiple, is the residual sum of squares, also called sum of squared errors or error sum of squares. The residual sum of squares is the difference between the observed and predicted values of the dependent variable, reflecting the variance in the dependent variable unexplained by the linear regression model.

In ordinary least squares regression, each residual is squared in value and sums taken of all of the observed residuals squared to create the residual sum of squares, denoted SSE. The residual sum of squares indicates the sum of squares not accounted for by the linear model. It describes the variation of the observations from the prediction line. Residual sum of squares (SSE), in mathematical expression, is $\sum (Y_i - \hat{Y}_i)^2$, with Y_i = observed values and $\hat{Y}_i$ = predicted values.

A numeric example of using residual sum of squares is provided in the following narrative. In a hypothetical study of weight loss among four people, the dependent variable is the weight loss (Y) and the independent variable is the exercise (X). Each of the four people experiences a reduction in weight, measured in pounds, over a 2-week time frame, as reflected in Table 1, column Y . Column X reflects the total observed amount of exercise, measured in hours, performed by each individual over the course of 2 weeks. The column labeled $\hat{Y}$ is the predicted value of Y , based on the prediction line. The column labeled $(Y - \hat{Y})$ indicates the individual residuals between each observed versus predicted value of Y . Finally, the column $(Y - \hat{Y})^2$ provides the squared residuals. By totaling all of the squared residuals, the residual sum of squares can be determined. In this case, that value is 677.

Residual sum of squares is useful for measuring the accuracy of regression prediction. As the prediction equation improves with predicted values closer to the observed values, the residuals of each observation tend to decrease, and subsequently, the residual sum of squares gets smaller.

Residual sum of squares can be used to determine the COEFFICIENT OF DETERMINATION, denoted r^2 for bivariate models, which indicates the proportional reduction in error based on using the linear prediction equation instead of the sample mean to predict values of the dependent variable. The equation for the coefficient of

Table 1 Example of Residual Sum of Squares

Observation	X	Y	$\hat{Y}$	$(Y - \hat{Y})$	$(Y - \hat{Y})^2$
1	7	28	14	14	196
2	15	12	30	-18	324
3	8	5	16	-11	121
4	10	14	20	-6	36

determination is $(TSS - SSE)/TSS$, with TSS = total sum of squares and SSE = residual sum of squares. For multiple regression, the same formula is used to calculate the coefficient of multiple determination, denoted R^2 .

The residual sum of squares plays a role in determining the significance of the coefficient of determination. The pertinent test statistic is called the F RATIO, and its equation is

$$\frac{\frac{R^2}{k}}{\frac{1-R^2}{n-(k+1)}},$$

with R^2 = the coefficient of determination, k = the number of explanatory variables in the model, and n = the sample size. Furthermore, the residual sum of squares can be used to compare complete and reduced models in multiple regression. The equation for the test statistic, also the F test, is

$$\frac{\frac{SSE_r - SSE_c}{k-g}}{\frac{SSE_c}{n-(k+1)}},$$

with SSE_r = residual sum of squares for the reduced model, SSE_c = residual sum of squares for the complete model, k = the number of explanatory variables in the complete model, g = the number of explanatory variables in the reduced model, and n = the sample size. This test allows the user to determine which model is better for accurately predicting the values of the dependent variable.

RESPONDENT

A respondent is the individual chosen to provide answers to survey questions. In many cases, a one-to-one correspondence exists between the sampling units that appear on a **SAMPLING FRAME**, the respondents, and the study **POPULATION** members or units on which the researchers want to report. In these cases, researchers can choose a sample from a list of individual study population members that can and are eligible to participate in the research project. When this is the case, the sampling process uniquely identifies the respondents. For example, specific public school principals could be identified as respondents for a survey of principals' attitudes and behaviors by sampling from a list of schools, because presumably, each school has one and only one principal. In this case, the sampling unit, the respondent, and the **UNIT OF ANALYSIS** uniquely identify each other.

There are three reasons why the respondent may be different from the sampled unit:

1. The sampling units are clusters or aggregations of the individual units of analysis.
2. The survey is administered in a manner that does not allow the respondent to answer questions directly even though the respondent is capable of providing answers.
3. Some or all of the study population is incapable of providing responses.

Each of these reasons, and some solutions for them, will be addressed below.

SAMPLED UNITS ARE AGGREGATIONS

Many surveys, such as those using **RANDOM DIGIT DIALING** telephone surveys or area **PROBABILITY SAMPLING** for personal interviews (Henry, 1990; Lavrakas, 1987), identify households or other clusters of individuals from which a specific respondent must be selected. To select the person who answers the phone or the door as the respondent would bias the sample, because some family members (often females) are more likely to answer than others. Therefore, social scientists have devised several types of objective procedures to choose an eligible household member (usually 18 or over and residing in the household) to respond to the survey. Three methods are most often employed to minimize systematic bias: the Kish

procedure, the Trodahl-Carter procedure, and the last birthday procedure (Czaja, Blair, & Sebestile, 1982; O'Rourke & Blair, 1983). For example, the National Election Studies (NES) have used the Kish procedure to select an eligible voter as the respondent from each household that is identified through the sampling procedures. Interview procedures for the NES do not allow substitution for the eligible voter initially selected.

In some cases, respondents are systematically selected based upon criteria that are important for the study, such as selecting the most knowledgeable household member or a specific member of the household. This is frequently the case when the respondent is asked not only about his or her own attitudes and behaviors but also about other individuals or the collective (e.g., household). For example, Hess (1985) indicated that

preferred respondents for the Surveys of Consumer Finances, which were concerned with the collection of financial data, were heads of spending units; only when the head was unavailable for the duration of the interviewing period was an interview to be taken with the wife of the head. (p. 53)

SURVEY PROCEDURES EXCLUDE CERTAIN RESPONDENTS

Some surveys are administered in ways that preclude the sample's study population members from responding. Interviews that are conducted only in English preclude responses from non-English speakers. In these cases, the researcher has a choice to allow a surrogate to answer—for example, to ask an English-speaking family member to translate for the study population member when possible—or to exclude non-English speakers from the interviews. Either choice can **BIAS** the responses, and the researcher must decide which approach minimizes study bias or must reconsider administering the survey in languages other than English. The limitations of surveys not only apply to language differences but also to study population members with hearing impairments or speaking difficulties.

STUDY POPULATION MEMBERS UNABLE TO RESPOND

Often, the study population members, or at least some of those chosen for the sample, are incapable

of responding to the survey. For example, studies of young children often rely on parents or teachers to provide responses for the children. In some cases, such as studies of the elderly or seriously ill, some of the sampled study population members may not be able to answer the questions. Researchers must decide whether to allow surrogates to provide or assist in providing answers, or to allow NONRESPONSE BIAS from omitting the responses of those unable to provide them for themselves.

In most surveys where listed samples are used, the sampling unit is the respondent, and additional procedures are not required to specify the respondent. However, two of the most popular forms of sampling used in the social sciences, area probability sampling and random digit dialing, require additional procedures to select a respondent because these procedures identify households, not individuals. In many cases, survey researchers have eligible study population members who will be excluded from the survey without accommodation of some type. In recent years, as the non-English-speaking proportion of English-speaking countries has increased, efforts have been expanded to increase the number of individuals who can provide survey responses. Cost and the capacity to develop procedures for accommodations, translate instruments, and administer the surveys are issues for social researchers to consider as decisions about accommodation are reached.

RESPONSE BIAS

With a psychological rating scale or self-report, a response bias is the tendency for a person to inject idiosyncratic, systematic biases into his or her judgments. These biases introduce subjectivity that distorts the judgments. If those BIASES occur across measures of different variables, they will distort observed relations between them (see METHOD VARIANCE). It should be kept in mind that people vary in their tendencies to exhibit response biases.

With scales that deal with aspects of the self, perhaps the most well-studied response bias is SOCIAL DESIRABILITY. This is the tendency to respond to items about self in a socially acceptable direction, regardless of the truth. Social desirable response bias will be seen only in items that are socially sensitive and do not occur universally. For example, one will tend to see this bias in ratings of psychological adjustment but not job satisfaction (Spector, 1987). In addition to a response bias, social desirability has been identified as the personality variable of need for approval (Crowne & Marlowe, 1964). Individuals who have a high need for the approval of others tend to respond in a socially desirable direction on questionnaires.

With rating scales that involve judgments about others, the most common response bias is *halo*, which is the tendency to rate all dimensions for the same individual the same regardless of true variation. Thus, a person exhibiting this bias might rate one person high on all dimensions and another low on all dimensions, even though each person might vary across dimensions. This might be due to the rater making a global judgment about each person and then assuming the person fits the global judgment on all dimensions. This sort of response bias is distinct from RESPONSE SETS (e.g., leniency or severity) in that the latter are independent of the item or rating target. For example, with instructor grading of students, a response set would be the tendency to rate all students the same (e.g., to be lenient and give all high grades). A response bias would be the tendency to inject subjectivity in the rating of each individual, giving those liked inflated grades and those disliked deflated grades.

Rating bias is inferred from patterns of responses by participants, but it is not always possible to accurately distinguish bias from accurate judgments. For example, with halo bias, it has been recognized that

in many situations, there can be real relations among different dimensions. In the employee job performance domain, researchers have distinguished true halo, or real relations among dimensions of performance, from illusory halo, which involves rater biases (see Latham, Skarlicki, Irvine, & Siegel, 1993).

RESPONSE EFFECTS

Response effects is a general term that covers a range of responses to SURVEY questions that is independent of the purposes of the question asked. Thus, things like the context effect of a question (i.e., what other types of related questions are in the survey?); ORDER EFFECTS (i.e., is the question before or after related questions?); memory effects (i.e., how well can the respondent remember from question to question?); wording effects (i.e., do changes in the wording of the question elicit different responses?); SOCIAL DESIRABILITY effects (i.e., are respondents giving what they think is the “right” answer?); and RESPONSE SETS (i.e., favoring a certain response category regardless of the question asked) are all examples of response effects. In a sense, these response effects are all sources of error.

—Michael S. Lewis-Beck

RESPONSE SET

With a psychological self-report or rating scale, a response set is the tendency to exhibit a particular pattern of response independent of the question being asked or the stimulus (person) being judged. For example, with a multiple-choice test format, a response

set might be to favor one of the lettered choices, for example, choice “3” or “c.”

There are several identified response sets. With self-report scales, *acquiescence* is the tendency to say yes (with yes/no items) or agree (with agree/disagree items) regardless of item content. A person exhibiting this set in the extreme will agree with both favorable and unfavorable items, although this means his or her responses are in conflict. It is possible to have a non-acquiescence set, in which the person disagrees with all items regardless of content.

There are three response sets that have been noted with scales in which people are asked to rate several dimensions of others’ behavior, such as evaluating the annual performance of employees or the abilities of students applying for graduate school. *Leniency* is the tendency to rate all individuals high on the dimension of interest. It can be seen where a rater, for example, tends to use only the top two choices on a five-point rating scale, such as instructors who award only grades of “A” or “B.” *Severity* is the opposite, where the rater gives only low ratings, such as instructors who give only “D” and “F” grades. *Central tendency* is the tendency to use only the middle of the scale, such as an instructor who tends to give mostly “C” grades and few, if any, “A” or “F” grades.

Although in theory, response sets are patterns of response independent of the item being asked or the real level of what is being judged, it seems unlikely that such sets are truly independent of content. Rohrer (1965), for example, was able to demonstrate that the acquiescence response set was not really independent of content but occurred within items of the same instrument and not across different instruments. In other words, an individual who exhibited a response set for one instrument did not exhibit it for other instruments. Spector (1987) showed that the tendency to agree with both favorable and unfavorable items was quite rare. It seems more likely that people exhibit RESPONSE BIAS, in which their patterns of response are affected by the items asked and the targets of what is being judged.

RETRODUCTION

This logic of inquiry is found in the version of REALISM associated with the work of Harré (1961) and Bhaskar (1979), versions also referred to as transcendental or CRITICAL REALISM. Retroduction has been identified by Harré and Bhaskar as overcoming the deficiencies of the logics of INDUCTION and deduction to offer causal explanations. They have also argued that it has been the basis for the development of past significant scientific explanations.

Retroduction entails the idea of going back from, below, or behind observed patterns or regularities to discover what produces them. Both Bhaskar and Harré rejected POSITIVISM's pattern model of explanation, that is, that explanation can be achieved by establishing regularities, or constant conjunctions. For them, establishing such regularities is only the beginning of the process. What is then required is to locate the structures or mechanisms that have produced the regularity. These structures and mechanisms are the tendencies or powers of things to act in a particular way. The capacity of a thing to exercise its powers, or the likelihood that it will, depends on whether or not the circumstances are favorable.

According to Bhaskar (1979), new mechanisms belong to a domain of reality that has yet to be observed. In order to discover these mechanisms, it is necessary to build hypothetical MODELS of them such that, if they were to exist and act in the postulated way, they would account for the phenomena being examined. These models constitute hypothetical descriptions that, it is hoped, will reveal the underlying mechanisms. Hence, these mechanisms can be known only by first constructing ideas about them. Retroduction identifies this process.

Building these hypothetical models is a creative activity involving disciplined scientific imagination and the use of analogies and metaphors. Once a model has been constructed, the researcher's task is to establish whether the structure or mechanism that it postulates actually exists. This may involve testing predictions based on the assumption that it does exist, and perhaps devising new instruments to observe it. The major value of the hypothetical model is that it gives direction to research; the retroductive researcher, unlike the inductive researcher, has something to look for.

The logic of retroduction has been used in the natural sciences in the discovery of previously unknown causal mechanisms, such as atoms and viruses. It has been applied by Harré in his ETHOGENIC approach to social psychology (see also Harré & Secord, 1972), and by Pawson in a realist form of social explanation based on a combination of the views of Harré and Bhaskar (Pawson & Tilley, 1997). The notion of retroduction and its social scientific applications are reviewed by Blaikie (1993, 2000).

Because retroduction is a relatively new notion in the social sciences, it has yet to attract serious criticism. However, given its foundation on critical realism, criticisms of the latter may also be leveled at retroduction. For the most part, these criticisms are likely to come from adherents to other PARADIGMS.

RHETORIC

The term *rhetoric* refers both to the persuasive character of discourse and to the long-established tradition of studying oratory. Political speeches, for example, are instances of rhetoric in the first sense because they are communications designed to persuade. Also, political speeches can be studied by the discipline of rhetoric, which will aim to demonstrate how speakers use discursive devices to try to convince their hearers.

The study of rhetoric dates back to ancient times. Aristotle and Cicero, for instance, analyzed the nature of oratory and sought to provide systematic, practical guidance for aspiring public speakers. In Europe during the Middle Ages, rhetoric was one of the three basic subjects of school curriculum, alongside mathematics

and grammar. By the time of the Renaissance, rhetoric was becoming the study of written literature, with rhetoricians devoting much effort to coding various figurative uses of language. By the late 19th century, the new disciplines of linguistics, psychology, and sociology were beginning to displace rhetoric from its preeminent place in the study of language and persuasion.

Classical rhetoric was essentially premethodological, for it did not provide analysts with a set of methodological procedures in the modern sense. This was one reason why the rhetorical tradition seemed to be in terminal decline. However, thinkers such as Kenneth Burke and Chaim Perelman were able to revive the traditions of classical rhetoric in the mid-20th century. This new rhetoric has had one very important consequence for the human and social sciences—the new rhetoricians have extended rhetoric from the traditional topics of oratory and literary texts to encompass the study of all discourse, including academic and scientific writing.

In particular, the “rhetoric of inquiry” has sought to show that the sciences and the social sciences are deeply rhetorical enterprises (Nelson, Megill, & McCloskey, 1987). Even disciplines that pride themselves on being “factual” and “scientific” use rhetorical devices in their technical reports. For example, Deirdre McCloskey applied Kenneth Burke’s rhetorical theory to the discipline of economics in her important book *The Rhetoric of Economics* (originally published in 1986 under the name of Donald McCloskey). She argues that economists habitually use figures of speech such as metaphor and metonymy, and that they employ mathematical formulae as ornamental devices of persuasion. Economists use such devices to convince readers of the factual, scientific nature of their conclusions. Other researchers have examined the rhetorical conventions of psychological, sociological, mathematical, and biological writing.

The rhetoric of inquiry shows how pervasive rhetoric is in human affairs (Billig, 1996). Inevitably, the exposure of rhetoric in academic writing has critical implications for disciplines that officially claim to be factual and thereby supposedly nonrhetorical. Moreover, the rhetoric of inquiry demonstrates that sciences and social sciences do not just comprise methodology and theory. Writing practices are crucial, although these are often treated as natural by practitioners. The extent to which the practices of writing, and thus the particular rhetorics of individual disciplines, influence

the content of theory and the practice of methodology is, at present, a matter of debate.

RHO

Rho is a POPULATION parameter that represents the population correlation coefficient of the PEARSON’S CORRELATION COEFFICIENT. Suppose there are N cases in a population, and each one of the cases has a value for RANDOM VARIABLE X and for random variable Y . In other words, there are N pairs of (X, Y) in a population. The population correlation coefficient between both variables X and Y (denoted as ρ_{XY}) is defined as

$$\frac{\text{Cov}(X, Y)}{\sigma_X \sigma_Y}$$

or

$$\frac{\sum z_{X_i} z_{Y_i}}{N},$$

which are the same mathematically. σ_X^2 and σ_Y^2 are the true variances of variables X and Y , which can be obtained from

$$\sigma_X^2 = \frac{\sum (X_i - \mu_X)^2}{N}$$

and

$$\sigma_Y^2 = \frac{\sum (Y_i - \mu_Y)^2}{N},$$

where μ_X and μ_Y are the population means of variable X and variable Y , respectively. $\text{Cov}(X, Y)$ is the true covariance of the population, defined as

$$\frac{\sum (X_i - \mu_X)(Y_i - \mu_Y)}{N}.$$

z_{X_i} and z_{Y_i} are Z-SCORES of X and Y for case i , defined as

$$z_{X_i} = \frac{X_i - \mu_X}{\sigma_X}$$

Figure 1 Frequency Distributions of Sample Correlation Coefficients Based on Six Different Sample Sizes, Given $\rho_{XY} = 0$

and

$$z_{Y_i} = \frac{Y_i - \mu_Y}{\sigma_Y}.$$

The population correlation coefficient can vary from 1 to -1 . Positive values of ρ_{XY} suggest that an increase of variable X is accompanied by an increase

of variable Y , and vice versa. In contrast, negative values of ρ_{XY} suggest that an increase of variable X is accompanied by a decrease of variable Y , and vice versa. A zero value of ρ_{XY} indicates there is no linear relationship between variables X and Y . Note that a zero value of ρ_{XY} is only a necessary rather than a

Table 1 Descriptive Results of Monte Carlo Simulations Based on Six Sample Sizes

Sample Sizes	Standard Deviation	Minimum Value	Maximum Value	Range	20th Percentile	50th Percentile	Mean	75th Percentile
20	0.2296202	-.7116160	.7270468	1.4386628	-.15944200	.004433800	-0.004665	.154351575
40	0.1538721	-.4491220	.4629634	.9120854	-.10791425	-.007544000	-0.000989	.098734075
80	0.113721	-.3216850	.3848182	.7065032	-.07750950	-.000134150	0.0002926	.076961525
160	0.0815591	-.2577240	.2692735	.5269975	-.05719025	-.001642500	-0.001815	.048942200
500	0.0451057	-.1584070	.1985341	.3569411	-.02901675	.001465750	0.0016551	.031811050
1000	0.0304901	-.0784490	.0944031	.1728521	-.02242350	.000527350	0.0000912	.021553250

sufficient condition for the INDEPENDENCE of variables X and Y . Hence, the zero value of ρ_{XY} does not imply the independence of variables X and Y . However, if both variables are determined to be independent of each other, ρ_{XY} must equal zero.

A correlation coefficient (r) based on a SAMPLE extracted from the population is often not the same as its population correlation coefficient (ρ). Imagine we randomly SAMPLE a group of 20 pairs of (X, Y) from a population, given $\rho_{XY} = 0$, and record the Pearson correlation coefficient calculated based on the formula

$$\frac{\sum X_i Y_i - \frac{\sum X_i \sum Y_i}{n}}{\sqrt{[\sum X_i^2 - \frac{(\sum X_i)^2}{n}][\sum Y_i^2 - \frac{(\sum Y_i)^2}{n}]}}.$$

Using the same procedure, we repeatedly select a sample of 20 pairs of (X, Y) 1,000 times, followed by sampling 40, 80, 160, 500, and 1,000 pairs of (X, Y) 1,000 times, respectively. Frequency distributions of 1,000 sample correlation coefficients given six different sample sizes are depicted in Figure 1. Although the six distributions are symmetrical overall and resemble one another, the range of sample correlation coefficients increases when sample size decreases. As seen in Table 1, the range of sample correlation coefficients decreases from -0.71 to -0.08 and from 0.72 to 0.09 when the sample size increases from 20 to 1,000. Furthermore, when the sample size increases, the means of the sample correlation coefficients are closer to the population rho, given $\rho_{XY} = 0$. Comparisons among distributions when ρ_{XY} equals nonzero values will be described in detail in Pearson's correlation coefficient.

ROBUST

Robust in statistical estimation means *insensitive* to *small* departures from the idealized assumptions for which the ESTIMATOR is optimized. The word “small” can mean either a *small* departure for all or almost all the data points, or large departures for a proportionally *small* number of data points.

—Tim Futing Liao

ROBUST STANDARD ERRORS

Statistical inferences are based on both observations and assumptions about underlying distributions and relationships between variables. If a model is relatively insensitive to small deviations from these ASSUMPTIONS, its PARAMETER ESTIMATIONS and STANDARD ERRORS can be considered robust. In some cases, the violation of an assumption affects only the standard errors. For example, violation of the ORDINARY LEAST SQUARES (OLS) assumptions of nonconstant error variance and independence produces UNBIASED parameter estimates but inconsistent standard errors. In other words, the regular OLS standard errors are not reliable, thus calling into question tests of statistical significance. One way of overcoming this problem is to use robust standard errors.

Robust standard errors were first developed to compensate for the existence of an unknown pattern of HETEROSKEDASTICITY that cannot be totally eliminated. There are several methods for calculating heteroskedasticity-consistent standard errors; these are known variously as White, Eicker, or Huber standard errors. Most of these are variants on the method originally proposed by White (1980), which uses the heteroskedasticity-consistent covariance matrix (HCCM). The HCCM matrix estimator is

$$V(b) = (X'X)^{-1} X' \hat{\Phi} X (X'X)^{-1},$$

where $\hat{\Phi} = \text{diag}[e_i^2]$, and the e_i are the OLS residuals.

Because the HCCM is found without a formal model of the heteroskedasticity, relying instead on only the regressors and residuals from the OLS for its computation, the White correction method can be easily adapted to many different applications. For example, robust standard errors can also be used to relax the independence assumption for data from clustered samples. Moreover, robust standard errors (e.g., Newey-West standard errors) can also improve statistical inference from pooled TIME-SERIES data with AUTOCORRELATED errors and from PANEL data.

Some cautions about the use of robust standard errors are necessary. First, not all robust estimators of variance perform equally well with small sample sizes (for a detailed discussion, see Long & Ervin, 2000). Perhaps more importantly, robust standard errors should not be seen as a substitute for careful model specification. In particular, if the pattern of heteroskedasticity is known, it can often be corrected more effectively—and the model estimated more efficiently—using WEIGHTED LEAST SQUARES. Similarly, although robust standard errors can be used for clustered data, greater information about the pattern in such data—such as the variance due to the clustering—can be obtained using MULTILEVEL modeling.

Finally, REGRESSION with robust standard errors should not be confused with “robust regression,” which refers to regression models that are resistant to skewed distributions and influential cases. With such models, both the estimates and the standard errors are different from those obtained from OLS regression.

—Robert Andersen

ROLE PLAYING

Role playing is a technique commonly used by researchers studying interpersonal behavior in which researchers assign research participants to particular roles and instruct those participants to act *as if* a set of conditions were true.

The use of role taking has a long history in social science research and was used in some of the early classic social psychological experiments by Kurt Lewin (1939/1997), Stanley Milgram (1963), and Phillip Zimbardo (Haney, Banks, & Zimbardo, 1973). For example, Zimbardo and colleagues set up a mock prison in the basement of the Stanford psychology department and randomly assigned undergraduate volunteers to serve in the role of either prisoner or guard. To increase the realism of the role assignments, those assigned to be prisoners were “arrested” in their dorms or classes, required to wear prisoners’ uniforms, and held in makeshift “cells” in the mock prison. Those assigned to be guards wore their street clothes and were assigned props such as mirrored sunglasses, whistles, and batons. The responses to this role assignment were dramatic. The behavior of those assigned to be guards became more authoritarian and more aggressive, whereas the behavior of those assigned to be prisoners became more passive and more dependent. Ultimately, the researchers halted the experiment prematurely when several of the mock prisoners began to experience physiological symptoms of severe stress. In a more contemporary example, Johnson (1994) made use of a role-playing experiment to show that individuals assigned to be supervisors of a mock organization exhibited different conversational behaviors from individuals assigned to be subordinates in that organization.

The process of role playing in a social experiment can be likened to a COMPUTER SIMULATION, where the human mind serves as the processor rather than a

computer. These techniques capitalize on the human ability to engage in creative role taking—to implement certain rules of thought, feeling, and behavior—under certain assumed conditions. That humans might be effective at playing arbitrarily assigned roles is bolstered by Goffman's (1959) ideas about all social behavior being a form of dramatic performance. The use of role playing in research presumes that individuals have the capacity to effectively imagine how they might behave in a given set of circumstances. It also presumes that there is a relationship between how individuals feel and act under these simulated circumstances and how they might feel and act under the actual circumstances they are simulating. However, the VALIDITY of role playing in social science research does not depend on individuals' abilities to behave precisely the way that they might in the actual circumstances being simulated. Rather, the strength of most research that makes use of role assignments is in the comparison of behaviors between individuals who have been RANDOMLY ASSIGNED to occupy different roles. Thus, it is more often the observed *differences* between the behaviors, thoughts, and feelings of those occupying the different roles that is of more interest than the actual character of the role-based behavior.

ROOT MEAN SQUARE

Root mean square error (RMSE) is a measure of how well an estimator performs. If $\hat{\beta}$ is an estimator of β , the RMSE of $\hat{\beta}$ is given by

$$\text{RMSE}(\hat{\beta}) = E[(\hat{\beta} - \beta)^2]. \quad (1)$$

We can immediately note that if $\beta = E[\hat{\beta}]$, then this is identical to the variance of $\hat{\beta}$. Rewriting this and simplifying the right-hand side provides the following decomposition:

$$\begin{aligned} \text{RMSE}(\hat{\beta}) &= E[(\hat{\beta} - E[\hat{\beta}] + E[\hat{\beta}] - \beta)^2] \\ &= E[(\hat{\beta} - E[\hat{\beta}])^2 + (E[\hat{\beta}] - \beta)^2 \\ &\quad - 2(\hat{\beta} - E[\hat{\beta}])(E[\hat{\beta}] - \beta)] \\ &= E[(\hat{\beta} - E[\hat{\beta}])^2] + E[(E[\hat{\beta}] - \beta)^2] \\ &\quad - 2E[(\hat{\beta} - E[\hat{\beta}])(E[\hat{\beta}] - \beta)]. \end{aligned} \quad (2)$$

The last expression reduces to 0, leaving:

$$\text{RMSE}(\hat{\beta}) = \text{Var}(\hat{\beta}) + [\text{bias}(\hat{\beta})]^2. \quad (3)$$

Again, note that if $\hat{\beta}$ is an unbiased estimator of β , then $\text{RMSE}(\hat{\beta}) = \text{Var}(\hat{\beta})$.

This leads to a fundamental comparison between two estimators: $\hat{\beta}$ and $\hat{\beta}^*$ in cases where $\hat{\beta}$ is an UNBIASED estimator of β and $\hat{\beta}^*$ is a BIASED estimator of β , but has lower variance than $\hat{\beta}$. In this case, depending upon the relative VARIANCES of the two estimators, and the size of the bias of $\hat{\beta}^*$, $\hat{\beta}^*$ could have a lower RMSE than $\hat{\beta}$. In this case, we might prefer the biased estimator to the unbiased estimator if we want to minimize RMSE!

RMSE AND OLS

RMSE has another common usage. Some statistics packages will print out a value for RMSE with the output of OLS regressions, and other linear models. It is what is more commonly known as the standard error of the regression:

$$\text{RMSE} = \sqrt{\frac{\sum (\hat{Y} - Y)^2}{n - k}}. \quad (4)$$

This is an estimator of the STANDARD DEVIATION of the POPULATION disturbance. Or, if we have a typical OLS setup, where

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_k X_k + \varepsilon, \quad (5)$$

then RMSE is an estimate of σ , where σ^2 is the variance of ε .

Thus, RMSE provides information about one component of the errors we make with estimates: It is a measure of the STOCHASTIC component of error. RMSE is measured in the units of the dependent variable.

It gives us a measure of how well our model would fit the data-generating process if we knew the true PARAMETERS of the model. A large value of RMSE implies that a large amount of variance in the dependent variable is not explained by the model. And it means that even if we obtained very precise estimates of the model parameters, any PREDICTION we made would still have a large range of uncertainty around it.

RMSE is one component of the error of any point prediction made using MODEL estimates. The UNCERTAINTY about such a point prediction also needs to take into account the estimation error about the parameter estimates being used. Thus, in computing the uncertainty about any point estimate, $\hat{Y}_i$, the uncertainty in our estimates of $\hat{\beta}$ that go into Y_i could dwarf the stochastic uncertainty contained in RMSE.

RMSE is thus a measure of GOODNESS OF FIT. But it is a measure of goodness of fit of the model, not of the estimates. It is often compared to an alternative measure of fit, R -SQUARED (R^2). However, R^2 contains different information from RMSE. Whereas RMSE is an estimator of the stochastic component of variance, R^2 is a measure of the fit between the predicted and the observed values of Y in the sample. Mathematically, the two are related as follows:

$$\text{RMSE}^2 = \text{Var}(Y) - \text{Var}(\hat{Y}), \quad (6)$$

$$R^2 = \frac{\text{Var}(\hat{Y})}{\text{Var}(Y)}. \quad (7)$$

So, if we want to know how well we are able to fit the given sample of data, R^2 can be a useful measure. But to understand the amount of stochastic variance present, we need to look at RMSE. R^2 will vary depending upon the variance in the sample Y s, whereas RMSE will remain a consistent estimator of the stochastic variance across different samples. The distinction between RMSE and R^2 is described in more detail in Achen (1977) and King (1990).

ROTATED FACTOR. See FACTOR ANALYSIS

ROTATIONS

The different methods of FACTOR ANALYSIS first extract a set of factors from a data set. These factors are almost always orthogonal and are ordered according to the proportion of the VARIANCE of the original data that these factors explain. In general, only a (small) subset of factors is kept for further consideration, and the remaining factors are considered either irrelevant or nonexistent (i.e., they are assumed to reflect measurement error or noise).

In order to make the interpretation of the factors that are considered relevant, the first selection step is generally followed by a rotation of the factors that were retained. Two main types of rotation are used: orthogonal, when the new axes are also orthogonal to each other, and oblique, when the new axes are not required to be orthogonal to each other. Because the rotations are always performed in a subspace (the so-called factor space), the new axes will always explain *less* variance than the original factors (which are computed to be optimal), but obviously, the part of variance explained by the total subspace after rotation is the same as it was before rotation (only the partition of the variance has changed). Because the rotated axes are not defined according to a statistical criterion, their *raison d'être* is to facilitate the interpretation.

In this entry, the rotation procedures are illustrated using the loadings of variables analyzed with PRINCIPAL COMPONENTS ANALYSIS (the so-called R -mode), but the methods described here are valid also for other types of analysis and when analyzing the subjects' scores (the so-called Q -mode).

Before proceeding further, it is important to stress that because the rotations always take place in a subspace (i.e., the space of the retained factors), the choice of this subspace strongly influences the result of the rotation. Therefore, in the practice of rotation in factor analysis, the strong recommendation is to try several sizes for the subspace of the retained factors in order to assess the robustness of the interpretation of the rotation.

NOTATIONS

To make the discussion more concrete, rotations within the principal components analysis (PCA) framework are described. PCA starts with a data matrix denoted $\mathbf{Y}$ with I rows and J columns, where each row represents a unit (in general subjects) described by J measurements that are almost always expressed as Z -scores. The data matrix is then decomposed into scores (for the subjects) or components and loadings for the variables (the loadings are, in general, correlations between the original variables and the components extracted by the analysis). Formally, PCA is equivalent to the singular value decomposition of the data matrix as

$$\mathbf{Y} = \mathbf{P}\mathbf{\Delta}\mathbf{Q}^T, \quad (1)$$

with the constraints that $\mathbf{Q}^T\mathbf{Q} = \mathbf{P}^T\mathbf{P} = \mathbf{I}$ (where $\mathbf{I}$ is the identity matrix), and $\mathbf{\Delta}$ is a diagonal matrix with the so-called singular values on the diagonal. The orthogonal matrix $\mathbf{Q}$ is the matrix of loadings (or projections of the original variables onto the components), where one row stands for one of the original variables and one column for one of the new factors. In general, the subjects' score matrix is obtained as $\mathbf{F} = \mathbf{P}\mathbf{\Delta}$ (some authors use $\mathbf{P}$ as the scores).

ROTATING: WHEN AND WHY?

Most of the rationale for rotating factors comes from Thurstone (1947) and Cattell (1978), who defended its use because this procedure simplifies the factor structure and therefore makes its interpretation easier and more reliable (i.e., easier to replicate with different data samples).

Thurstone suggested five criteria to identify a simple structure. According to these criteria, still often reported in the literature, a matrix of loadings (where the rows correspond to the original variables and the columns to the factors) is simple if

1. each row contains at least one zero
2. for each column, there are at least as many zeros as there are columns (i.e., number of factors kept)
3. for any pair of factors, there are some variables with zero loadings on one factor and large loadings on the other factor
4. for any pair of factors, there is a sizable proportion of zero loadings
5. for any pair of factors, there is only a small number of large loadings.

Rotations of factors can (and used to) be done graphically, but are mostly obtained analytically and necessitate the mathematical specification of the notion of simple structure in order to implement it with a computer program.

ORTHOGONAL ROTATION

An orthogonal rotation is specified by a rotation matrix denoted $\mathbf{R}$, where the rows stand for the original factors and the columns for the new (rotated) factors. At the intersection of row m and column n we have the cosine of the angle between the original axis and the new one: $r_{m,n} = \cos \theta_{m,n}$. For example, the rotation illustrated in Figure 1 will be characterized by the following matrix:

$$\begin{aligned} \mathbf{R} &= \begin{bmatrix} \cos \theta_{1,1} & \cos \theta_{1,2} \\ \cos \theta_{2,1} & \cos \theta_{2,2} \end{bmatrix} \\ &= \begin{bmatrix} \cos \theta_{1,1} & -\sin \theta_{1,1} \\ \sin \theta_{1,1} & \cos \theta_{1,1} \end{bmatrix}, \end{aligned} \quad (2)$$

with a value of $\theta_{1,1} = 15$ degrees. A rotation matrix has the important property of being orthonormal because it corresponds to a matrix of direction cosines and therefore $\mathbf{R}^T\mathbf{R} = \mathbf{I}$.

Figure 1 An Orthogonal Rotation in Two Dimensions; the Angle of Rotation Between an Old Axis m and a New Axis n Is Denoted By $\theta_{m,n}$

VARIMAX

VARIMAX, which was developed by Kaiser (1958), is indubitably the most popular rotation method by far. For varimax, a simple solution means that each factor has a small number of large loadings and a large number of zero (or small) loadings. This simplifies the interpretation because, after a varimax rotation, each original variable tends to be associated with one (or a small number of) factors, and each factor represents only a small number of variables. In addition, the factors often can be interpreted from the opposition of few variables with positive loadings to few variables with negative loadings.

Formally, varimax searches for a rotation (i.e., a linear combination) of the original factors such that the *variance* of the loadings is maximized, which amounts to maximizing

$$V = \sum (q_{j,\ell}^2 - \bar{q}_{j,\ell}^2)^2, \quad (3)$$

with $q_{j,\ell}^2$ being the squared loading of the j th variable on the ℓ factor, and $\bar{q}_{j,\ell}^2$ being the mean of the squared loadings. (For computational stability, each of the loadings matrices is generally scaled to length one prior to the minimization procedure.)

OTHER ORTHOGONAL ROTATIONS

There are several other methods for orthogonal rotation such as the quartimax rotation, which minimizes the number of factors needed to explain each variable, and the equimax rotation, which is a compromise between varimax and quartimax. Other methods exist, but none approaches varimax in popularity.

AN EXAMPLE OF ORTHOGONAL VARIMAX ROTATION

To illustrate the procedure for a varimax rotation, suppose that we have five wines described by the average rating of a set of experts on their hedonic dimension—how much the wine goes with dessert and how much the wine goes with meat; each wine is also described by its price, its sugar and alcohol content, and its acidity. The data are given in Table 1.

A PCA of this table extracts four factors (with eigenvalues of 4.7627, 1.8101, 0.3527, and 0.0744, respectively), and a two-factor solution (corresponding to the components with an eigenvalue larger than unity)

Table 1 An (Artificial) Example for PCA and Rotation; Five Wines Are Described by Seven Variables

		<i>For</i>	<i>For</i>				
	<i>Hedonic</i>	<i>Meat</i>	<i>Dessert</i>	<i>Price</i>	<i>Sugar</i>	<i>Alcohol</i>	<i>Acidity</i>
Wine 1	14	7	8	7	7	13	7
Wine 2	10	7	6	4	3	14	7
Wine 3	8	5	5	10	5	12	5
Wine 4	2	4	7	16	7	11	3
Wine 5	6	2	4	13	3	10	3

Figure 2 PCA, Original Loadings of the Seven Variables for the Wine Example

explaining that 94% of the variance is kept for rotation. The loadings are given in Table 2.

The varimax rotation procedure applied to the table of loadings gives a clockwise rotation of 15 degrees (corresponding to a cosine of .97). This gives the new set of rotated factors shown in Table 3. The rotation procedure is illustrated in Figures 2, 3, and 4. In this example, the improvement in the simplicity of the interpretation is somewhat marginal, maybe because the factorial structure of such a small data set is already very simple. The first dimension remains linked to price, and the second dimension now appears more clearly as the dimension of sweetness.

Table 2 Wine Example: Original Loadings of the Seven Variables on the First Two Components

	<i>Hedonic</i>	<i>For Meat</i>	<i>For Dessert</i>	<i>Price</i>	<i>Sugar</i>	<i>Alcohol</i>	<i>Acidity</i>
Factor 1	−0.3965	−0.4454	−0.2646	0.4160	−0.0485	−0.4385	−0.4547
Factor 2	0.1149	−0.1090	−0.5854	−0.3111	−0.7245	0.0555	0.0865

Table 3 Wine Example: Loadings, After Varimax Rotation, of the Seven Variables on the First Two Components

	<i>Hedonic</i>	<i>For Meat</i>	<i>For Dessert</i>	<i>Price</i>	<i>Sugar</i>	<i>Alcohol</i>	<i>Acidity</i>
Factor 1	−0.4125	−0.4057	−0.1147	0.4790	0.1286	−0.4389	−0.4620
Factor 2	0.0153	−0.2138	−0.6321	−0.2010	−0.7146	−0.0525	−0.0264

OBLIQUE ROTATIONS

In oblique rotations, the new axes are free to take any position in the factor space, but the degree of correlation allowed among factors is, in general, small because two highly correlated factors are better interpreted as only one factor. Therefore, oblique rotations relax the orthogonality constraint in order to gain simplicity in the interpretation. They were strongly recommended by Thurstone but are used more rarely than their orthogonal counterparts.

For oblique rotations, the promax rotation has the advantage of being fast and conceptually simple. Its name derives from procrustean rotation because it tries to fit a *target* matrix that has a simple structure. It necessitates two steps. The first step defines the target matrix, almost always obtained as the result of a varimax rotation whose entries are raised to some power (typically between 2 and 4) in order to “force” the structure of the loadings to become bipolar. The second step is obtained by computing a least squares fit from the varimax solution to the target matrix.

Table 4 Wine Example: Promax Oblique Rotation Solution; Correlation of the Seven Variables on the First Two Components

	<i>Hedonic</i>	<i>For Meat</i>	<i>For Dessert</i>	<i>Price</i>	<i>Sugar</i>	<i>Alcohol</i>	<i>Acidity</i>
Factor 1	−0.8783	−0.9433	−0.4653	0.9562	0.0271	−0.9583	−0.9988
Factor 2	−0.1559	−0.4756	−0.9393	−0.0768	−0.9507	−0.2628	−0.2360

Even though, in principle, the results of oblique rotations could be presented graphically, they are almost always interpreted by looking at the correlations between the rotated axis and the original variables. These correlations are interpreted as loadings.

For the wine example, using as target the varimax solution raised to the fourth power, a promax rotation gives the loadings shown in Table 4. From these loadings, one can find that the first dimension once again isolates the price (positively correlated to the factor) and opposes it to the other variables: alcohol, acidity, “going with meat,” and hedonic component. The second axis shows only a small correlation with the first one ($r = -.02$). It corresponds to the “sweetness/going with dessert” factor. Once again, the interpretation is quite similar to the original PCA because the small size of the data set favors a simple structure in the solution.

Oblique rotations are much less popular than their orthogonal counterparts, but this trend may change as new techniques, such as *independent component analysis*, are developed. This recent technique, originally created in the domain of signal processing and NEURAL NETWORKS, derives directly from the data matrix an oblique solution that maximizes statistical independence.

ROUNDING ERROR

It is customary to round estimates off, up, or down. If an estimate is rounded off, then it is left with fewer digits. For example, an estimated income of \$67,542.67 might be rounded off to \$67,543, thus losing two digits. Also, note that, here, income is rounded up; the last 67 cents (.67) is rounded up to a whole dollar. Of course, if the original estimate had been \$67,542.38, we would have rounded down, to \$67,542. In all these instances of rounding—off, up, or down—some error is introduced. In the first and second instances, the error is .67; in the third instance, it is .38. A common example of rounding error occurs when column percentages are summed in a table, for they frequently sum to 99% or 101%, instead of the correct 100%. When that occurs, the analyst usually includes a footnote indicating that the percentages do not sum to 100 because of rounding error. The presence of rounding error is routine, not to say inevitable, and rarely causes difficulty, because the error is small and random. It is, of course, possible to round too much. For example, suppose we rounded the above income number to \$70,000. Now that income estimate contains a rounding error of nearly \$2,500. Thus, rounding error has increased, but is this too much error? The answer to that question depends on the RESEARCH QUESTION asked and the degree of precision the analyst desires. At the other extreme, it is possible to not round enough. For example, in most income studies, we would not need to know income measured to the penny. Indeed, to claim that we could estimate income to the penny may be giving a false sense of precision, denying the greater error inherent in the MEASUREMENT.

R-SQUARED

The R -squared (R^2) measures the explanatory or predictive power of a REGRESSION model. It is a GOODNESS-OF-FIT MEASURE, indicating how well the linear regression equation fits the data.

In regression analysis, it is important to evaluate the performance of the estimated regression equation. To what extent does it account for the phenomenon under study? The R^2 is the leading performance measure for a simple or MULTIPLE REGRESSION model. Suppose a policy analyst is studying public school expenditures in the 50 American states. The analyst posits a simple regression model, $Y = a + bX + e$, where Y is the DEPENDENT VARIABLE of per-pupil public school expenditures (in thousands of dollars) in each state in the year 2000, X is the INDEPENDENT VARIABLE of urbanization (percentage of population in cities larger than 25,000, as of the 2000 census), and e is the error term. The model argues that state public school outlays are accounted for, in part, by urbanization. ORDINARY LEAST SQUARES (OLS) estimation yields, hypothetically, the following results: $Y = 2.11 + .60X + e$, suggesting that for every additional percentage of urban population, a state expects to spend \$600 more. The R^2 , or coefficient of determination, for the equation is .42, which says that 42% of the variation in state public school expenditures is explained, or at least predicted, by urbanization.

The R^2 shows the gain in predicting Y knowing X , as opposed to not knowing X . Suppose that the analyst knows the scores on Y , but not the states to which they are attached, and tries to predict school expenditures state by state. The best guess, the one that minimizes the error, would always be the average of Y , that is, Y_m . This guess will be way off for most states, with a great distance from the observed expenditure score to the average expenditure score, that is, $(Y - Y_m)$. Adding all these distances together (after squaring to overcome the canceling out of the plus and minus signs), they represent the total prediction error not knowing X ; that is, total sum of squared deviations ($TSS = \sum(Y - Y_m)^2$).

Regression analysis promises reduction of this prediction error through knowledge of X and its linear

relationship to Y . For example, knowing a state's score on X is 30% urban, the prediction, $\hat{Y}$, is 20.21 ($\hat{Y} = 2.11 + 18.10 = 20.21$), not Y_m . The distance from the predicted Y to the mean Y , $(\hat{Y} - Y_m)$, is the improvement over the baseline prediction made possible by knowing X . This distance, squared and summed for all observations, is the reduction in prediction error attributable to application of the regression line; that is, regression sum of squared deviations ($RSS = \sum(\hat{Y} - Y_m)^2$). Unless the regression line predicts each case perfectly, some error will still remain: the distance from the observed Y and the predicted Y . These distances, squared then summed, represent the variation in Y that remains unexplained; that is, error sum of squared deviations ($ESS = \sum(Y - \hat{Y})^2$).

Total variation in the dependent variable, TSS, thus has two unique parts: RSS accounted for by the regression and ESS not accounted for by the regression. The R^2 reflects the regression portion as a share of the total, $RSS/TSS = R^2$. The statistic ranges from 1.0, when all variation is accounted for, to .00, when no variation is accounted for. With real-world data, the R^2 seldom reaches these extreme values. In the above example, we may say that 42% of the variation in public school expenditures is explained by urbanization. It is important to remember that this explanation may be more "statistical" than "causal." It could be that urbanization helps predict public school expenditure but does not really explain it in a theoretical sense. In such cases, it is more cautious, and perhaps more correct, to say that X merely "accounts for" so much variation in Y . In the bivariate regression case, the R^2 equals the CORRELATION coefficient squared (the r^2).

With a multiple regression equation, the R^2 is referred to as the coefficient of multiple determination. Again, it measures the linear goodness of fit of the model, ranging from 1.0 to .00. For example, when the multiple regression model, $Y = a + bX + cZ + e$, is estimated with OLS, the R^2 indicates the fit of a plane to the points in a three-dimensional space. For more than two independent variables, a hyperplane is fitted. The MULTIPLE CORRELATION coefficient, symbolized by R , is the square root of the R^2 and indicates the correlation of the ensemble of independent variables with the dependent variable.

When an independent variable is added to a regression model, the R^2 always increases. Some of this increase is due to chance, for adding independent variables uses DEGREES OF FREEDOM. Especially as the number of independent variables approaches the

sample size, the R^2 estimate will exaggerate the real fit of the model to the data. Most analysts report the ADJUSTED R -SQUARED for a multiple regression model, along with, or instead of, the R^2 itself. The adjusted R^2 will be smaller in magnitude than the R^2 , but seldom much smaller. Unlike the R^2 , the adjusted R^2 can show decreases as independent variables are added to a model. (Rarely, the adjusted R^2 can be negative, when the unadjusted fit is extremely low in the first place. The unadjusted R^2 has the possibility of being negative only if the constant term is forced to be zero.)

Analysts generally prefer a high R^2 , sensing that a better fit means a better explanation. However, that may or may not be true. R^2 maximization should not be an end in itself. Blind inclusion into a regression model of the variables that have a high correlation with the dependent variable may yield a high R^2 . But when that model is estimated on a subsequent sample, that high fit will likely plummet, because much of it came from chance variation in the first sample. A moderate, even low, R^2 is not necessarily bad. Certain kinds of data, such as public opinion surveys, do not generally admit of high fits. Regardless of data type, a low fit may simply mean that only a small portion of Y can be explained, the rest being random. There is a case where a low R^2 may be a bad sign, the case of NONLINEARITY. If the relationship follows a curve rather than a straight line, then linear specification and the R^2 assessment of model performance is inappropriate. Finally, a low R^2 for any model suggests the model will predict poorly.

The R^2 has been subjected to various criticisms. Some consider the baseline for prediction

comparison— Y_m —to be naive. Usually, however, it is difficult to come up with a better alternative baseline. Similarly, some object that it assesses only the linearity of model fit. However, it is often hard to improve on the linear specification in practice. A further issue is whether the R^2 of different models can be tested for STATISTICALLY SIGNIFICANT differences, in order to assess rival model specifications. This can be done if one model is possibly a nested subset of another larger model. Legitimate use of such significance tests depends partly on whether the R^2 is held to be a descriptive or inferential statistic. A few analysts reject the R^2 altogether, preferring the STANDARD ERROR OF ESTIMATE (SEE) of Y as a measure of goodness of fit. The difficulty with using the SEE measure alone is that it has no conventional theoretical boundary at the upper end (e.g., 1.0). As SEE gets larger, one knows there is more prediction error, but one does not know whether it has reached its maximum. In general, the two measures of fit should both be reported because they say somewhat different things.

S

SAMPLE

A sample is a subset of the elements or members of a POPULATION. It is employed to collect information from or about the elements in a way that the resulting information can represent the population from which it was drawn. Sampling is used as an efficient and cost-effective way to collect DATA that can both reduce costs as well as improve the quality of the resulting data.

Cost reduction comes from simply collecting information for fewer units of analysis. In the typical public opinion poll, a sample of size 1,000 represents only 1 in 288,400 citizens of the United States. A representative sample of this size would allow a researcher to estimate the average age of an American with some precision, and the information could be collected more rapidly than if a CENSUS were taken of the entire population.

Some of the savings derived from using a sample can be applied to improving data quality. It could be applied to improving coverage in implementing the original sampling design by reducing NONRESPONSE. Additional resources could be used for INTERVIEWER TRAINING to improve the administration of the QUESTIONNAIRE. And resources could also be applied to lengthening the questionnaire so that more questions could be asked about specific concepts, improving the RELIABILITY and VALIDITY of their measurement.

Every sample is evaluated by two key properties: its design and its implementation. In order to invoke the SAMPLING DISTRIBUTION and employ

CONFIDENCE INTERVALS and confidence levels, a researcher must use a probability design—one in which every element of the population has a known, nonzero chance of being selected. Nonprobability designs such as QUOTA SAMPLES, CONVENIENCE SAMPLES, or PURPOSIVE SAMPLES do not permit this.

Every sample design must be well implemented by devoting resources to contacting every element in order to collect data for or from it. The coverage or response rate reflects the proportion of the original number of elements in the sample for which information has been obtained. Even if a probability design is used, a low coverage rate may invalidate the use of the sample estimates because of a concern that the loss of information was systematic and not RANDOM. In samples used by the government, for example, socioeconomic status or housing status often represent systematic sources of ERROR because low-income or homeless people may be difficult to find. In public opinion polls, individuals who are not interested in politics may be more likely to refuse to participate in TELEPHONE SURVEYS than those who are interested, so the results may reflect those with intensely held attitudes more than the total population.

SAMPLING

The basic idea in sampling is **EXTRAPOLATION** from the part to the whole—from “the sample” to “the population.” (The population is sometimes rather mysteriously called “the universe.”) There is an immediate corollary: the sample must be chosen to fairly represent the population.

Methods for choosing samples are called “designs.” Good designs involve the use of probability methods, minimizing subjective judgment in the choice of units to survey. Samples drawn using probability methods are called “probability samples.”

BIAS is a serious problem in applied work; probability samples minimize bias. As it turns out, however, methods used to extrapolate from a probability sample to the population should take into account the method used to draw the sample; otherwise, bias may come in through the back door.

The ideas will be illustrated for sampling people or business records, but apply more broadly. There are sample surveys of buildings, farms, law cases, schools, trees, trade union locals, and many other populations.

SAMPLE DESIGN

Probability samples should be distinguished from “samples of convenience” (also called “grab samples”). A typical sample of convenience comprises the investigator’s students in an introductory course. A “mall sample” consists of the people willing to be interviewed on certain days at certain shopping centers. This too is a convenience sample. The reason for the nomenclature is apparent, and so is the downside: the sample may not represent any definable population larger than itself.

To draw a probability sample, we begin by identifying the population of interest. The next step is to create the “sampling frame,” a list of units to be sampled. One easy design is **SIMPLE RANDOM SAMPLING**. For instance, to draw a simple random sample of 100 units, choose one unit at random from the frame; put this unit into the sample; choose another unit at random from the remaining ones in the frame; and so forth. Keep going until 100 units have been chosen. At each step along the way, all units in the pool have the same chance of being chosen.

Simple random sampling is often practical for a population of business records, even when that population is large. When it comes to people, especially

when face-to-face interviews are to be conducted, simple random sampling is seldom feasible: where would we get the frame? More complex designs are therefore needed. If, for instance, we wanted to sample people in a city, we could list all the blocks in the city to create the frame, draw a simple random sample of blocks, and interview all people in housing units in the selected blocks. This is a “cluster sample,” the cluster being the block.

Notice that the population has to be defined rather carefully: it consists of the people living in housing units in the city, at the time the sample is taken. There are many variations. For example, one person in each household can be interviewed to get information on the whole household. Or, a person can be chosen at random within the household. The age of the respondent can be restricted; and so forth. If telephone interviews are to be conducted, **RANDOM DIGIT DIALING** often provides a reasonable approximation to simple random sampling—for the population with telephones.

CLASSIFICATION OF ERRORS

Since the sample is only part of the whole, extrapolation inevitably leads to **ERRORS**. These are of two kinds: sampling error (“random error”) and non-sampling error (“systematic **ERROR**”). The latter is often called “bias,” without connoting any prejudice.

SAMPLING ERROR results from the luck of the draw when choosing a sample: we get a few too many units of one kind, and not enough of another. The likely impact of sampling error is usually quantified using the “**SE**,” or **STANDARD ERROR**. With **PROBABILITY SAMPLES**, the **SE** can be estimated using (i) the sample design and (ii) the sample data.

As the “sample size” (the number of units in the sample) increases, the **SE** goes down, albeit rather slowly. If the population is relatively homogeneous, the **SE** will be small: the degree of heterogeneity can usually be estimated from sample data, using the standard deviation or some analogous statistic. Cluster samples—especially with large clusters—tend to have large **SEs**, although such designs are often cost-effective.

NON-SAMPLING ERROR is often the more serious problem in practical work, but it is harder to quantify and receives less attention than sampling error. Non-sampling error cannot be controlled by making the sample bigger. Indeed, bigger samples are harder to manage. Increasing the size of the

sample—which is beneficial from the perspective of sampling error—may be counter-productive from the perspective of non-sampling error.

Non-sampling error itself can be broken down into three main categories: (i) selection bias, (ii) non-response bias, and (iii) response bias. We discuss these in turn.

(i) **SELECTION BIAS** is a systematic tendency to exclude one kind of unit or another from the sample. With a convenience sample, selection bias is a major issue. With a well-designed probability sample, selection bias is minimal. That is the chief advantage of probability samples.

(ii) Generally, the people who hang up on you are different from the ones who are willing to be interviewed. This difference exemplifies non-response bias. Extrapolation from respondents to non-respondents is problematic, due to non-response bias. If the response rate is high (most interviews are completed), non-response bias is minimal. If the response rate is low, non-response bias is a problem that needs to be considered.

At the time of writing, US government surveys that accept any respondent in the household have response rates over 95%. The best face-to-face research surveys in the US, interviewing a randomly-selected adult in a household, get response rates over 80%. The best **TELEPHONE SURVEYS** get response rates approaching 60%. Many commercial surveys have much lower response rates, which is cause for concern.

(iii) Respondents can easily be led to shade the truth, by interviewer attitudes, the precise wording of questions, or even the juxtaposition of one question with another. These are typical sources of **RESPONSE BIAS**.

Sampling error is well-defined for probability samples. Can the concept be stretched to cover convenience samples? That is debatable (see below). Probability samples are expensive, but minimize selection bias, and provide a basis for estimating the likely impact of sampling error. Response bias and non-response bias affect probability samples as well as convenience samples.

TRADING NON-RESPONDENTS FOR RESPONDENTS

Many surveys have a planned sample size: if a non-respondent is encountered, a respondent is substituted.

That may be helpful in controlling sampling error, but makes no contribution whatsoever to reducing bias. If the survey is going to extrapolate from respondents to non-respondents, it is imperative to know how many non-respondents were encountered.

HOW BIG SHOULD THE SAMPLE BE?

There is no definitive statistical answer to this familiar question. Bigger samples have less sampling error. On the other hand, smaller samples may be easier to manage, and have less non-sampling error. Bigger samples are more expensive than smaller ones: generally, resource constraints will determine the sample size. If a pilot study is done, it may be possible to judge the implications of sample size for accuracy of final estimates.

The size of the population is seldom a determining factor, provided the focus is on relative errors. For example, the percentage breakdown of the popular vote in a US presidential election—with 200 million potential voters—can be estimated reasonably well by taking a sample of several thousand people. Of course, choosing a sample from 200 million people all across the US is a lot more work than sampling from a population of 200,000 concentrated in Boise, Idaho.

STRATIFICATION AND WEIGHTS

Often, the sampling frame will be partitioned into groupings called “strata,” with simple random samples drawn independently from each stratum. If the strata are relatively homogeneous, there is a gain in statistical efficiency. Other ideas of efficiency come into play as well. If we sample blocks in a city, some will be sparsely populated. To save interviewer time, it may be wise to sample such blocks at a lower rate than the densely-populated ones. If the objective is to study determinants of poverty, it may be advantageous to over-sample blocks in poorer neighborhoods.

If different strata are sampled at different rates, analytic procedures must take sampling rates into account. The “Horvitz-Thompson” estimator, for instance, weights each unit according to the inverse of its selection probability. This estimator is unbiased, although its variance may be high. Failure to use proper weights generally leads to bias, which may be large in some circumstances. (With convenience samples, there may not be a convincing way to control bias by using weights.)

An **ESTIMATOR** based on a complex design will often have a larger variance than the corresponding estimator

based on a simple random sample of the same size: clustering is one reason, variation in weights is another. The ratio of the two variances is called the DESIGN EFFECT.

RATIO AND DIFFERENCE ESTIMATORS

Suppose we have to audit a large population of claims to determine their total audited value, which will be compared to the “book value.” Auditing the whole population is too expensive, so we take a sample. A relatively large percentage of the value is likely to be in a small percentage of claims. Thus, we may over-sample the large claims and under-sample the small ones, adjusting later by use of weights. For the moment, however, let us consider a simple random sample.

Suppose we take the ratio of the total audited value in the sample claims to the total book value, then multiply by the total book value of the population. This is a “ratio estimator” for the total audited value of all claims in the population. Ratio estimators are biased, because their denominators are random: but the bias can be estimated from the data, and is usually offset by a reduction in sampling variability. Ratio estimators are widely used.

Less familiar is the “difference estimator.” In our claims example, we could take the difference between the audited value and book value for each sample claim. The sample average—dollars per claim—could then be multiplied by the total number of claims in the population. This estimator for the total difference between audited and book value is unbiased, and is often competitive with the ratio estimator.

Ratio estimators and the like depend on having additional information about the population being sampled. In our example, we need to know the number of claims in the population, and the book value for each; the audited value would be available only for the sample. For stratification, yet other information about the population would be needed. We might use the number of claims and their book value, for several different strata defined by size of claim. Stratification improves accuracy when there is relevant additional information about the population.

COMPUTING THE STANDARD ERROR

With simple random samples, the sample average is an unbiased estimate of the population

average—assuming that response bias and non-response bias are negligible. The SE for the sample average is generally well approximated by the SD of the sample, divided by the square root of the sample size.

With complex designs, there is no simple formula for variances; procedures like “the jackknife” may be used to get approximate variances. (The SE is the square root of the variance.) With non-linear statistics like ratio estimators, the “delta method” can be used.

THE SAMPLING DISTRIBUTION

We consider probability samples, setting aside response bias and non-response bias. An estimator takes different values for different samples (“sampling variability”); the probability of taking on any particular value can, at least in principle, be determined from the sample design. The probability distribution for the estimator is its “sampling distribution.” The expected value of the estimator is the center of its sampling distribution, and the SE is the spread. Technically, the “bias” in an estimator is the difference between its expected value and the true value of the estimand.

SOME EXAMPLES

In 1936, Franklin Delano Roosevelt ran for his second term, against Alf Landon. Most observers expected FDR to swamp Landon—but not the *Literary Digest*, which predicted that FDR would get only 43% of the popular vote. (In the election, FDR got 62%.) The *Digest* prediction was based on an enormous sample, with 2.4 million respondents. Sampling error was not the issue. The problem must then be non-sampling error, and to find its source, we need to consider how the sample was chosen.

The *Digest* mailed out 10 million questionnaires and got 2.4 million replies—leaving ample room for non-response bias. Moreover, the questionnaires were sent to people on mailing lists compiled from car ownership lists and telephone directories, among other sources. In 1936, cars and telephones were not as common as they are today, and the *Digest* mailing list was overloaded with people who could afford what were luxury goods in the depression era. That is selection bias.

We turn now to 1948, when the major polling organizations (including Gallup and Roper) tapped Dewey—rather than Truman—for the presidency. According to one celebrated headline,

DEWEY AS GOOD AS ELECTED, STATISTICS CONVINCE ROPER

The samples were large—tens of thousands of respondents. The issue was non-sampling error, the problem being with the method used to choose the samples. That was QUOTA SAMPLING. Interviewers were free to choose any subjects they liked, but certain numerical quotas were prescribed. For instance, one interviewer had to choose 7 men and 6 women; of the men, 4 had to be over 40 years of age; and so forth.

Quotas were set so that, in the aggregate, the sample closely resembled the population with respect to gender, age, and other control variables. But the issue was, who would vote for Dewey? Within each of the sample categories, some persons were more likely than others to vote Republican. No quota could be set on likely Republican voters, their number being unknown at the time of the survey. As it turns out, the interviewers preferred Republicans to Democrats—not only in 1948 but in all previous elections where the method had been used.

Interviewer preference for Republicans is another example of selection bias. In 1936, 1940, and 1948, Roosevelt won by substantial margins: selection bias in the polls did not affect predictions by enough to matter. But the 1948 election was a much closer contest, and selection bias tilted the balance in the polls. Quota sampling looks reasonable: it is still widely used. Since 1948, however, the advantages of probability sampling should be clear to all.

Our final example is a proposal to adjust the U. S. census. This is a complicated topic, but in brief, a special sample survey (“Post Enumeration Survey”) is done after the census, to estimate error rates in the census. If error rates can be estimated with sufficient accuracy, they can be corrected. The Post Enumeration Survey is a stratified block cluster sample, along the lines described above. Sample sizes are huge (700,000 people in 2000), and sampling error is under reasonable control. Non-sampling error, however, remains a problem—relative to the small errors in the census that need to be fixed. For discussion from various perspectives, see Imber (2001).

SUPER-POPULATION MODELS

Samples of convenience are often analyzed as if they were simple random samples from some large, poorly-defined parent population. This unsupported

assumption is sometimes called the “super-population model.” The frequency with which the assumption has been made in the past does not provide any justification for making it again, and neither does the grandiloquent name. Assumptions have consequences, and should only be made after careful consideration: the problem of induction is unlikely to be solved by fiat. For discussion, see Berk and Freedman (1995).

An SE for a convenience sample is best viewed as a de minimis error estimate: if this were—contrary to fact—a simple random sample, the uncertainty due to randomness would be something like the SE. However, the calculation should not be allowed to divert attention from non-sampling error, which remains the primary concern. (The SE measures sampling error, and generally ignores bias.)

SOME PRACTICAL ADVICE

Survey research is not easy; helpful advice will be found in the references below. Much attention needs to be paid in the design phase. The research hypotheses should be defined, together with the target population. If people are to be interviewed, the interviewers need to be trained and supervised. Quality control is essential. So is documentation. The survey instrument itself must be developed. Short, clear questions are needed; these should be worded so as to elicit truthful rather than pleasing answers. Doing one or more pilot studies is highly recommended. Non-response has to be minimized; if non-response is appreciable, a sample of non-respondents should be interviewed. To the maximum extent feasible, probability methods should be used to draw the sample.

SAMPLING BIAS. See SAMPLING ERROR

SAMPLING DISTRIBUTION

The sampling distribution of a particular statistic is the FREQUENCY DISTRIBUTION of possible values of the statistic over all possible samples under the sampling design. This distribution is important because it is equivalent to a PROBABILITY DISTRIBUTION, given that just one survey is usually carried out. Therefore, the single realized survey statistic is a RANDOM observation from the sampling distribution. Knowledge of the sampling distribution allows a researcher to calculate the probability that the statistic will fall within any specified range of values.

Two important characteristics of a sampling distribution are its location and its DISPERSION. If the mean of the DISTRIBUTION is located at the true population value of a PARAMETER, of which the sample statistic is an estimate, then the sample statistic is said to be an UNBIASED estimator of the population parameter. In other words, the estimate will be right “on average,” though not necessarily in any one realization. The greater the dispersion of the distribution, the more likely it is that a realized statistic—even if it is

an unbiased estimator—will be discrepant from the population parameter by any given magnitude. A common way to measure dispersion is by the variance of the distribution. Sample designers strive to minimize the variance of estimators because this minimizes the probability that the selected sample will produce an estimate considerably in error from the population parameter. In summary, sampling distributions of estimators should ideally be unbiased and have small variance.

Sampling distributions can be estimated only for designs that employ RANDOM SAMPLING. With non-probability designs, the concept of a probability distribution is not defined. With random sampling designs, estimators are known to be unbiased (under randomization inference), so only the variance of the sampling distribution remains of concern.

In practice, for a wide range of survey statistics, provided that the sample size is not too small, the sampling distribution turns out to approximate toward the NORMAL (Gaussian) DISTRIBUTION. In consequence, the known properties of the normal distribution can be used to provide approximate CONFIDENCE INTERVALS for estimates. For example, 95% of the possible estimates will lie within plus or minus 1.96 standard deviations of the mean of the distribution (Figure 1).

Figure 1 A Sampling Distribution

NOTES: The mean of the sampling distribution (expected value) is 135.0. The two vertical lines represent the mean plus or minus 1.96 standard deviations (the standard deviation is 3.98). Of all the possible estimates that could be obtained, 2.5% of them are less than 127.2, 2.5% are greater than 142.8, and the remaining 95% lie between these values.

Therefore, it is necessary only to estimate the STANDARD DEVIATION of the sampling distribution—more commonly referred to as the STANDARD ERROR of the estimate. However, the normal approximation is not universally good. In particular, certain types of estimates may tend to have a nonsymmetrical sampling distribution. In this situation, other methods must be used to estimate CONFIDENCE INTERVALS, such as replication methods.

It is important to realize that under a single sample design, different sample statistics will have different sampling distributions. Therefore, even if it is possible to estimate the mean and variance of sampling distributions prior to carrying out a survey, it will rarely be possible to select a design that is optimal for all statistics. Sample designs are typically a compromise, chosen to produce sampling distributions that are likely to be good enough for most of the estimates required.

SAMPLING ERROR

Any attempt to use a sample SURVEY as a means of studying a larger POPULATION of interest runs the risk that the selected sample will not have exactly the same characteristics as the population. In consequence, sample-based estimates will not necessarily take the same numeric values as the population PARAMETERS of which they are ESTIMATES. The term *sampling error* is used to refer to this general tendency of sample estimates to differ from the true population values. A main aim of sample design is to minimize the risk of sample characteristics differing greatly from population characteristics.

In the context of quantitative sample surveys using random sampling methods (see RANDOM SAMPLING), sampling error also has a more specific meaning. It refers to the expected deviation, under a particular specified sample design, of a particular sample

statistic from the equivalent population parameter. This expected deviation will have two components, a component due to random sampling error (variability, or VARIANCE) and a component due to systematic sampling error (BIAS). Therefore, for unbiased sample designs (or, strictly, unbiased sample-based estimators), sampling error is simply equal to sampling variance. Often, STANDARD ERRORS of survey estimates (the square root of the sampling variance) are estimated and presented as estimates of sampling error. Standard errors can be used in the construction of CONFIDENCE INTERVALS. More generally, MEAN SQUARED ERROR is used as a measure of sampling error. Mean squared error is defined as

$$\begin{aligned} \text{MSE}(y) &= E[y - E(y)]^2 + [E(y) - Y]^2 \\ &= \text{Var}(y) + \text{Bias}^2(y) \end{aligned} \quad (1)$$

where the sample statistic y is used to estimate the population parameter Y . The MSE is the sum of the variance and the squared bias of the estimate.

This quantity is, of course, specific to a particular estimate under a particular sample design. In practice, it can never be known for most survey estimates because the magnitude of bias is not known (if it was known, it could be removed from the survey estimate, so there would be no need to use a biased estimator). It is largely for this reason that attempts to estimate sampling error are typically restricted to estimation of the variance of an estimate. Also, there are many situations in which sampling bias can reasonably be assumed to be zero, or negligible. The variance of estimates can be readily estimated from survey data, provided that important design features such as clustering, stratification, and design weighting are indicated on the data and taken into account appropriately in the calculation. For most of the commonly used sample designs, the form of the variance is known; therefore, standard estimation methods can be used. For particularly complex designs, or designs that are not well specified, it may be necessary to use a REPLICATION method to estimate empirically the variance of sample statistics. Methods such as JACKKNIFE, BOOTSTRAP, and balanced repeated replications are increasingly available in commercial software packages.

Sampling error is only one component of total survey error. The total survey error of a statistic is the expected deviation of the statistic from the equivalent population parameter. This incorporates not only error due to sampling, but also error due to noncoverage;

NONRESPONSE; and MEASUREMENT (interviewer error, respondent error, instrument error, processing error). In many situations, although sampling bias may be negligible, other sources of bias may be important. For this reason, standard errors can be misleading as a guide to the accuracy of survey estimates.

SAMPLING FRACTION

The sampling fraction indicates the fraction, or proportion, of units on a SAMPLING FRAME that are selected to form the sample for a survey. If there are N units on the frame and n in the sample, then the sampling fraction is n/N .

Sampling fraction is sometimes confused with selection probability. A sampling fraction of n/N does not necessarily imply that each unit had a selection probability of n/N . It is possible that different units among the N had different selection probabilities. A sampling fraction simply indicates the overall fraction of population units that ended up in the sample, regardless of how they came to be selected.

Some surveys will use different sampling fractions for different parts of the POPULATION (strata). This is known as disproportionate stratified sampling. It is typically employed for the purpose of increasing the SAMPLE size of groups that are small in the population but of particular analytical interest. Using a larger sampling fraction in strata with larger population variance can also improve the precision of estimates (see also STRATIFIED SAMPLE).

In the case of systematic sampling, the sampling fraction reflects not only the outcome of the sampling process but also the process itself, and is equal in meaning to the selection probability. A sampling fraction of $1/A$ means that every A th unit on the list was (or will be) selected. A , the reciprocal of the sampling fraction, is referred to as the *sampling interval* (see also SYSTEMATIC SAMPLING).

The sampling fraction has a negligible effect on the precision of survey estimates unless it becomes

SAMPLING FRAME

A sampling frame is a list or other device used to define a researcher's POPULATION of interest. The sampling frame defines a set of elements from which a researcher can select a SAMPLE of the target population. Because a researcher rarely has direct access to the entire population of interest in social science research, a researcher must rely upon a sampling frame to represent all of the elements of the population of interest.

Generally, sampling frames can be divided into two types, list and nonlist. Examples of list frames include a list of registered voters in a town, residents listed in a local telephone directory, or a roster of students enrolled in a course. Examples of nonlist frames include a set of telephone numbers for RANDOM DIGIT DIALING and all housing units in a defined geographic area for area PROBABILITY SAMPLING. Random digit dial (RDD) frames are designed specifically for TELEPHONE SURVEY research, where interviewers call the households associated with selected telephone numbers to conduct an interview. An area probability sampling frame is primarily used only for in-person SURVEY research, where interviewers approach each sampled unit to complete an interview. Most list samples can be used with any data collection mode, including in-person, telephone, and mail surveys.

The two most important goals that a good sampling frame achieves are comprehensiveness and accuracy. Comprehensiveness refers to the degree to which a

sampling frame covers the entire target population. For example, a residential listing in a local telephone directory typically does not provide an adequate sampling frame to represent all residents in a given area. Telephone directories do not include residents with unlisted telephone numbers or those who have only recently begun telephone service. In contrast, an RDD sampling frame provides a current set of both listed and unlisted telephone numbers associated with a given set of telephone exchanges. Although the RDD frame is superior to the directory listing in this respect, neither frame includes residents in households without telephone service.

Accuracy refers to the degree to which a sampling frame includes correct information about the elements of the target population it covers. Telephone directories, town lists, and other kinds of lists often include information that is inaccurate because of data entry errors, outdated information, and other problems. The accuracy of the information provided by such lists can affect the quality of a sampling frame independent of its comprehensiveness.

Sampling frames that are not sufficiently comprehensive and accurate can be a major source of BIAS in any research project. Bias can occur when the sampling frame either excludes elements that are members of the target population or includes elements that are *not* members of the target population. To the extent that incorrectly excluded or included elements differ from the population of interest, these differences can produce bias. If a researcher can identify elements that have been incorrectly included in a sampling frame, the researcher can simply eliminate these elements from the sampling process. Yet researchers often have little information about elements excluded from the sampling frame that are members of the target population. Missing elements that cannot be identified and recovered have no chance of being selected into the sample. As a result, samples drawn from frames with missing elements often do not sufficiently represent the target population.

SAMPLING IN QUALITATIVE RESEARCH

SAMPLING is the deliberate selection of the most appropriate participants to be included in the study, according to the way that the theoretical needs of the study may be met by the characteristics of the participants. In qualitative inquiry, attention to sampling is crucial for the attainment of rigor and takes place throughout the research process.

TYPES OF SAMPLES

Samples are classified according to the means by which participants are selected from the population. In qualitative inquiry, this selection procedure is a *deliberate* rather than a *random* process.

Convenience Sample

Convenience sampling is selecting the sample by including participants who are readily available and who meet the study criteria. A CONVENIENCE SAMPLE may be used at the beginning of the sampling process, when the investigator does not know the pertinent characteristics for criteria for sample selection, or it is used when the number of participants available is small. For example, we may be exploring the experience of children who have had cardiac surgery, or of ventilator-dependent schoolchildren, and this patient population within a given geographic area is low. When *all* available participants have been included in the study (e.g., *all* children in a particular classroom), it is referred to as a *total* sample.

Minimally, to be included as a participant in a qualitative interview, participants must be willing and able to reflect on an experience, articulate their experience, and have time available without interruption to be interviewed. Problems may arise when using a total sample: When a participant is invited or volunteers to be interviewed, the researcher does not know if the participant will meet that minimal criterion for a “good” participant. If we include all participant interviews in the initial sample, we have not used any screening procedures. On the other hand, if the researcher starts an interview and finds that the participant is not a good informant and does not have the anticipated experiences nor knows the information we are seeking, then we practice *secondary selection* (Morse, 1989). In this

case, the researcher politely completes the interview. The tape is labeled and set aside. The researcher does not waste time and research funds TRANSCRIBING the tape. The interview is not incorporated into the data set, but neither is the tape erased. The audiotape is stored, just in case it makes sense and is needed at a later date.

Theoretical Sample

This is the selection of participants according to the theoretical needs of the study. If the researcher has identified a comparative research question and knows the dimensions of the comparison to be conducted, THEORETICAL SAMPLING may be used at the commencement of data collection. For example, the researcher may use a two-group design comparing participants—for instance, comparing single mothers who are continuously receiving unemployment with those who periodically work and sporadically claim benefits. Thus, theoretical sampling enables comparison of the two sets of data and the identification of differences between the two groups. As analysis proceeds, categories and themes form, some areas of analysis will be slower to saturate than others or may appear thin. A theoretical sample is the deliberate seeking of participants who have particular knowledge or characteristics that will contribute data to categories with inadequate data, referred to as *thin* areas of analysis. Alternatively, the investigator may develop a conjecture or HYPOTHESIS that could be tested by seeking out and interviewing people with characteristics that may be compared or contrasted with other participants. An example may be the findings from the previous study of single, unemployed mothers, which revealed that those mothers who returned to work were more resilient than those who remained unemployed. Because this sample had too few participants to verify this emerging finding, the researchers must then deliberately seek out participants who fit that criterion, in order to saturate those categories. This type of theoretical sampling, in which participants are deliberately sought according to individual characteristics, is sometimes also referred to as PURPOSIVE SAMPLING.

Negative Cases

Sampling for negative cases is the deliberate seeking of participants who are exceptions to the developing theoretical scheme. If we carry our unemployed single mother example further, a negative case, such as a

mother who returned to work periodically, but who does *not* demonstrate the identified traits of resilience, may emerge. In order for the developing theory to be complete and valid, negative cases must be purposefully selected until the negative category is saturated, and logical explanation for these exceptions included in the theory.

THE PROGRESSION OF QUALITATIVE SAMPLING

As noted, in qualitative inquiry, sampling continues throughout the study, forming a responsive link between data collection and analysis. Initially, the investigator may practice *open sampling*—deliberately seeking as much variation as possible within the limits of the topic. This variation enables the scope of the problem or the phenomena to be delineated. Later, as sampling proceeds, as understanding is gained, and as categories begin to emerge, the sampling strategies may change to theoretical sampling in order to verify emerging theoretical formulations. Thus, sampling continues until the theory is thick, dense, and saturated.

Thus far, we have referred to sampling as the process of selecting participants for the study. In qualitative inquiry, sampling also occurs during the process of analysis, in the selection of and attending to particular data. In qualitative analysis, all data are not treated equally—the researcher attends to some data, data that may be richer or provide more explanation that contributes to the developing insights. Other data may be used to support or refute these developing notions, and yet still other data may not contain any relevant information, and therefore may not be attended to in a particular phase of analysis and consequently ignored. At the writing-up stage, the researcher purposely selects the best examples of quotations to illustrate points made in the developing argument.

WHY RANDOM SAMPLES ARE INAPPROPRIATE

Randomization means that anyone in the identified group is a potential participant in the study. Yet qualitative researchers know that all participants would not make equally good participants. We know that some participants may be more reluctant to participate than others (they may not have time, may not want to think about the topic, may feel ill, and so forth), and some may be more or less articulate and

reflective than others. Of greatest concern, not all have equal life experiences that are of interest to the interviewer. Because qualitative data are expensive to obtain—interviews are very time consuming and must be transcribed; text is clumsy and time consuming to analyze, compared with test scores and quantitative analysis—qualitative researchers cannot afford to collect data that are weak or off the topic. In addition, the process of randomization does not give researchers the opportunity to control the useful amount of data they collect. Because knowledge of a topic is not randomly distributed in the population, collecting data by chance would result in excessive data being collected on topics that are generally known, and inadequate data on less common topics. Thus, the data contained will be excessive in some areas (and therefore waste resources) and inadequate in others. Furthermore, the common findings, that is, the amount of data in topics that occur frequently, may overwhelm and mute certain less common and equally important features, thus actually biasing and invalidating the analysis.

EVALUATION OF THE SAMPLE

Those new to qualitative research have a number of concerns: How many participants? How many observations? How many data will be needed? How many data depends on a number of factors, including the quality of the data, the nature of the phenomenon, and the scope of the study. Consider the following principles:

1. *The broader the scope of the study, the greater the amount of data that is needed.* A common trap for a new investigator is to not delineate the problem before beginning the study, so that he or she tries to study everything—which, of course, means that many more participants and many more data will be needed to reach saturation. On the other hand, prematurely delineating the topic may result in excluding important aspects of the problem or simplifying the problems, and be equally invalid.

2. *The better the quality of the interviews, the fewer interviews that will be needed.* Ideally, interviews should be conducted with an appropriate sample. If the sample is carefully selected, and if the information obtained is minimally irrelevant, is insightful, and has excellent detail, then the investigator will be able to stop sampling sooner than if he or she obtains interviews that are vague, irrelevant, ambiguous, or contradictory.

3. *There is an inverse relationship between the amount of data obtained from each participant and the number of participants.* Methods that use in-depth interviewing methods such as interactive interviews, which involve interviewing participants three times for more than 1 hour each, will reach saturation more quickly, with fewer participants, than if they used SEMISTRUCTURED INTERVIEWS and presented participants with only a set number of question stems.

HOW DO YOU TELL WHEN YOU HAVE SAMPLED ENOUGH?

There is an adage that the qualitative researcher may stop sampling when he or she is bored (Morse & Richards, 2002). That or, saturation is reached when no new data appear, and when the researcher has “heard it all.” Saturation occurs more quickly when the sample is adequate and appropriate, as well as when the study has a narrow focus.

Adequacy

Adequacy refers to enough data. Data must replicate within the data set. That is, it is not satisfactory to hear something from someone once—these ideas should be verified by other participants, or verified by other means (documents, observations, and so forth). These verifications may be in the same form or in different forms—for instance, different stories that illustrate similar points that the researcher is trying to make. Adequate data are essential for concept and theory constructions—in fact, it is harder to develop categories with thin, inadequate data than with adequate data, for it is difficult to see patterns without REPLICATION, and themes if there are gaps.

Appropriateness

Appropriateness refers to the deliberate selection of the best participants to be involved in the study. Appropriate sampling in qualitative inquiry is ongoing throughout the study, using the methods of purposeful and theoretical sampling described above.

SAMPLING VARIABILITY. See **SAMPLING ERROR**

SAMPLING WITH (OR WITHOUT) REPLACEMENT

SIMPLE RANDOM SAMPLES are, by convention, samples drawn without replacement. **SAMPLING** without replacement means that when a unit is selected from the population to be included in the sample, it is not placed back into the pool from which the sample is being selected. In sampling without replacement, each unit in the population can be selected for the sample once and only once. For example, if we are drawing a sample of 10 balls from a group of 999 balls, we could place the balls in a box, each numbered with a unique number between 1 and 999. Then, the box is shaken and the first ball selected in a fair process. If we are drawing a sample of 10 balls, the number on the first one—in this example, 071—is noted and the ball is set aside. Nine other balls are selected using the same process, and each time, the one that is selected is set aside. Because the balls are set aside after being selected for the sample, this is sampling without replacement. By convention, sampling without replacement is assumed in most samples taken for the purposes of social science research.

Although this procedure may seem to be common sense, from the standpoint that it seems to serve no purpose for a member of the study population to appear more than once in a single sample, an alternative procedure, sampling with replacement, has some very nice properties and is actually very important for statistical theory. Sampling with replacement, using the same shaken container of balls as the earlier example, would involve selecting each ball—this time, say, the first one is 802—recording its number, and placing the ball back into the box. This time, 802 is eligible for selection again. A benefit from the standpoint of statistical theory is that each draw for selecting a sample member is completely **INDEPENDENT** of the selection of any other

unit. Each population member can be selected on any draw, thus, the **PROBABILITY** of selection is the same for each draw.

For sampling without replacement, each draw after the first draw is dependent on the prior draws. Although the dependence of future selections on previous draws is relatively minor when selecting **PROBABILITY SAMPLES** without replacement, some issues should be considered. For example, an issue of independence arises in the selection of a **CONTROL GROUP** in randomized **EXPERIMENTS**. If the **TREATMENT** group is selected first, then, from a technical standpoint, the selection of the sample for the control group is dependent on the selection of the treatment group. If the randomization procedures are not completely without **BIAS**, as happened with the lottery for the draft into the US military in 1969 (McKean, 1987, p. 75), this can create a bias. In most cases, the occurrence of such bias can be investigated by examining the differences between the treatment and control groups on characteristics that are related, according to theory, to the outcome variables. The differences can show whether the bias is likely to affect the experiment's results, but can never be disproved with certainty.

Another concern with practical implications is the calculation of the **STANDARD ERROR** for samples without replacement. Technically speaking, when a sample without replacement is drawn, a finite population control (fpc) is required to compute the standard error for the sample. The formula for a simple random sample is

$$s_{(e)} = (1 - f)^{1/2} s / n^{1/2},$$

where

$s_{(e)}$	is the standard error of estimator e
$1 - f$	is the finite population correction factor
f	is the sampling fraction, or n/N
s	is the estimate of the standard deviation
n	is the size of the sample

The influence of the fpc depends upon the size of the population and the size of the sample relative to the population. Generally, the fpc is of no practical significance when the sample is less than 5% of the population (Henry, 1990; Kish, 1965). If, for example, a sample of 1,200 is to be drawn from a population of 10,000 students in a school district, the fpc would reduce the sampling error by approximately .94, a meaningful amount. If the same-size sample was being drawn from a population of 1.4 million students in an

entire state, the fpc would reduce the sampling error by .9996, an insignificant amount that effectively makes the fpc = 1. In most cases for social science research, the fpc can be omitted, but when drawing a sample from a small population, it can significantly reduce the sampling error for samples drawn without replacement.

SATURATED MODEL

A saturated model has as many parameters as data values. The predicted or fitted values from a saturated model are equal to the data values; that is, a saturated model perfectly reproduces the data. A single observation or data point can be thought of as one piece of information; therefore, in a sample of n data points, there are n pieces of information. Each statistic or parameter computed from n data points uses up one piece of information. When a model has as many parameters as there is information in the data, the model is saturated, and the model is said to have zero DEGREES OF FREEDOM.

As a small example, suppose that we have a sample of three observations— $x_1 = 3$, $x_2 = 5$, and $x_3 = 10$ —from some population, and we want to fit the model $x_i = \mu + \beta_i$ to the data where μ and β_i are parameters of the model. The β_i s may have a different value for each observation (i.e., $i = 1, 2$, and 3). A reasonable estimate of μ is the sample mean; that is,

$\bar{x} = (3 + 5 + 10)/3 = 6$, which uses up one piece of information and leaves two pieces of information to estimate the β_i s. With the remaining two pieces of information, we can estimate two β_i s by taking the difference between a data value and the sample mean. For example, $\hat{\beta}_1 = (x_1 - \bar{x}) = (3 - 6) = -3$, and $\hat{\beta}_2 = (x_2 - \bar{x}) = (5 - 6) = -1$. We now have three estimated parameters, $\bar{x}$, $\hat{\beta}_1$, and $\hat{\beta}_2$, which uses up all the information in the data. The value of the last parameter, β_3 , is computed using $\hat{\beta}_1$ and $\hat{\beta}_2$, along with the fact that the sum of differences between the data values and their mean equals zero; that is,

$$\begin{aligned}\sum_{i=1}^3 (x_i - \bar{x}) &= (x_1 - \bar{x}) + (x_2 - \bar{x}) + (x_3 - \bar{x}) \\ &= \hat{\beta}_1 + \hat{\beta}_2 + \hat{\beta}_3 = 0.\end{aligned}$$

Solving this for $\hat{\beta}_3$ gives us $\hat{\beta}_3 = -(\hat{\beta}_1 + \hat{\beta}_2) = -(-3 - 1) = 4$. Using the estimated parameters in the model yields predicted values that are exactly equal to the data values; that is,

$$\begin{aligned}\hat{x}_1 &= 6 - 3 = 3 \\ \hat{x}_2 &= 6 - 1 = 5 \\ \hat{x}_3 &= 6 + 4 = 10.\end{aligned}$$

Models are fitted to data to provide a summary or description of data, to produce an equation for predicting future values, or to test hypotheses about the population from which the data were sampled. Generally, simpler models are preferred because they smooth out the unsystematic variation present in data, which results from having only a sample from a population. Although saturated models are extremely accurate, they do not distinguish between unsystematic and systematic variation in data.

Saturated models play an important role in global GOODNESS-OF-FIT statistical tests for nonsaturated models. All nonsaturated models are special cases of the saturated model. Consider two common statistics for testing model goodness-of-fit to data: PEARSON'S CHI-SQUARE STATISTIC,

$$\chi^2 = \sum_{i=1}^N (x_i - \hat{x}_i)^2 / \hat{x}_i,$$

and the LIKELIHOOD RATIO STATISTIC,

$$L^2 = \sum_{i=1}^N x_i \log(x_i / \hat{x}_i),$$

where x_i equals an observed measurement on individual i , $\hat{x}_i$ equals the predicted or modeled measurement from an unsaturated model, and N equals the total number of observations. In both cases, the nonsaturated model's predicted values are compared to data values, which are the predicted values of the saturated model.

SCALE

A scale is a composite measure of some underlying CONCEPT. Many phenomena in social science are theoretical CONSTRUCTS that cannot be directly measured by a single VARIABLE. To understand the causes, effects, and implications of these phenomena, the researcher must develop a VALID and RELIABLE empirical indicator of these constructs. This empirical indicator is called a *scale*. In this sense, the scale is composed of a set of measurable items that empirically captures the essential meaning of the theoretical construct.

Good scales are data reduction devices that simplify the information and, in one composite, measure the direction and intensity of a construct. They are usually constructed at the ORDINAL level of measurement, although some can be at the INTERVAL level. Because they are constructed of more than one indicator of a particular phenomenon, they increase both the reliability and the validity that would be attainable if the individual indicators were used in analysis.

Several possible models can be used to combine items into a scale. These include THURSTONE scaling, LIKERT scaling, and GUTTMAN scaling. The method chosen depends on the purpose that the scale is intended to serve.

SCALING has three related but distinct purposes. In the first case, scaling may be intended to test a specific HYPOTHESIS (e.g., that a single dimension, party identification, structures voters' choice of presidential candidate). In this case, the scaling model is used as

a criterion to evaluate the relative fit of a given set of observed data to a specific model.

Another purpose for scaling is to describe a data structure. If a political scientist attempted to discover the underlying dimensions (e.g., social, economic, cultural, etc.) of the United States' electoral system, this would be an exploratory analysis rather than a hypothesis-testing approach.

The third purpose for scaling is to construct a measure on which individuals can be placed and then relate their scores on that scale to other measures of interest.

Scaling models may be used to scale people, stimuli, or both people and stimuli. The Likert scale is a scaling model that scales only subjects. Broadly, any SCALE obtained by summing the response scores of its constituent items is called a Likert or "summative" scale, or a linear composite. An examination in a mathematics class is an example of a linear composite. The scale (test) score is found by adding the number of correct answers to the individual items (questions). The composite score on the scale (test) is a better indicator of the student's knowledge of the material than is any single item (question).

Thurstone's interest lay in measuring and comparing stimuli when there is no evident logical structure. The Thurstone scaling model is an attempt to identify an empirical structure among the stimuli. To do this, Thurstone scaling uses human judgments. Individuals are given statements, maybe as many as 100. These "judges" order the statements along an underlying dimension. Those statements that produced the most agreement among the judges are selected as the items to be included in the scale. These remaining items (say, 20) should cover the entire latent continuum. These items are then presented to subjects, who are asked to identify those they accept or with which they agree. The average scale value of those items chosen represents the person's attitude toward the object in question.

The final type of scale to be discussed here, Guttman scaling (or scalogram analysis or cumulative scaling), is a procedure designed to order both items and subjects with respect to some underlying cumulative dimension. It was developed to be an empirical test of the unidimensionality of a set of items. The underlying logic of this method is cumulative; that is, by knowing a subject's score on the scale, that subject's response to each item is known. If the subject's score is 3, the researcher knows not only that the subject answered three items "correctly," but also which three, namely,

the first, second, and third items. Much of Guttman scaling analysis concerns what to do with deviations from the perfect scale.

This has been a cursory discussion of scales—what they are and the purposes for which they are used. Scales are used extensively in social research, and their construction and interpretation bears some study.

SCALING

Scaling methods comprise procedures that assign numbers to properties or characteristics of objects. As such, “scaling” seems to be very similar to “measurement” (which is also commonly defined as “assigning numbers to objects”). The difference between the two is subtle, but important: MEASUREMENT can usually be reduced to some kind of physical counting operation. For example, the width of an object is assessed by determining the number of uniformly sized rods (or uniformly spaced calibration marks on a single rod) that can be placed alongside the object, spanning the entire distance from one side to the other. Similarly, the mass of an object is determined by the number of uniform weights that are required to balance it in a scale.

GENERAL OBJECTIVES

Scaling, in contrast, is used to quantify phenomena that cannot be counted directly. For example,

scaling techniques have been employed to measure the attitudes of survey respondents, the severity of crimes, the prestige of occupations, and the ideology of legislators. In each of these cases, we believe that the phenomenon in question (i.e., attitudes, severity, prestige, ideology) actually exists. But none of these things can be “counted” in a manner similar to the way one would assess the calibrations on a ruler or a scale. It is for such phenomena that scaling methods exist.

There is no single technique called “scaling.” Instead, there is a very wide variety of scaling models. The common characteristic is that they all seek to recover systematic structure in real-world observations by representing elements of the input data matrix (i.e., observations, stimuli, variables, etc.) as objects (usually, points or vectors) within a geometric space. Thus, a scale is an abstract model of data that are, themselves, culled from empirical observations. The way that one proceeds from observations, to data, to the geometric model depends upon the specific scaling strategy.

In any case, performing a scaling analysis is similar to putting together a jigsaw puzzle. Like the pieces of a puzzle, individual data points provide only fragmentary, limited information. When puzzle pieces are put together, the result is a picture that an observer can comprehend and understand. Similarly, when observations are combined into some geometric structure, the resultant “picture” shows the relative positions of the objects in the data matrix and thereby helps the analyst understand the contents and implications of the data themselves.

DATA AND SCALING METHODS

How does one choose a specific scaling model for a particular data analysis situation? The answer depends upon the researcher's interpretation of information contained within the input data matrix and the type of model that he or she wants to construct to represent that information. The two most common types of data matrices are *multivariate* and *similarities*. Multivariate data refer to a matrix in which the rows and columns represent different objects (usually, observations and variables), and the cell entries provide scores for one set of objects with respect to the other (observations' variable values). For example, survey respondents' ratings of the incumbent president on each of 10 characteristics would be an example of multivariate data.

With similarities data, the rows and columns represent the same objects (hence, the matrix is actually square), and the cell entries indicate the degree to which the row and column entries are similar to each other: for example, an experimental subject's opinion about the degree to which each of 10 foods tastes similar to each of the others. But similarities data can represent many other things besides actual similarity among objects. For scaling purposes, such diverse phenomena as distances, covariances, and the degree to which different objects share common characteristics can all be interpreted as similarities data. Probably the most familiar type of similarities data is a CORRELATION matrix (which measures the pairwise "similarity" of variables).

If the researcher has multivariate data and wants to obtain a unidimensional scale of the rows *or* the columns, then LIKERT SCALING (also called SUMMATED RATING SCALING) would be appropriate. If the objective is a unidimensional representation of the rows *and* columns, then GUTTMAN SCALING (based upon the cumulative scaling model) would be a useful technique. If the analyst is interested in locating the rows and columns within multiple dimensions, then PRINCIPAL COMPONENTS ANALYSIS could be used. Turning to similarities data, if the input is a correlation MATRIX, then FACTOR ANALYSIS is often the appropriate model: Correlations are modeled as functions of the angles between vectors (which represent the variables). MULTIDIMENSIONAL SCALING (MDS) is used for most other kinds of similarities data: In that case, similarities are modeled as distances between points in a space (with greater similarity corresponding to smaller distance).

Although less common, there are many other types of data besides multivariate and similarities—and scaling methods appropriate for them. For example, a data matrix in which the rows and columns represent the same objects and each cell entry shows the degree to which that row object exceeds the column object (or vice versa) on some specified characteristic is sometimes called *stimulus comparison* data. This kind of information can be scaled using any of several THURSTONE SCALING techniques. A matrix in which the rows and columns represent different objects, with cell entries that indicate the proximity of each row element to each column element, is sometimes called *preferential choice* data. It can be used as input to an unfolding analysis.

DATA REDUCTION

Researchers tend to employ scaling procedures for four complementary reasons. First, there is data reduction. Analysts are often confronted with massive amounts of information, often too much to be readily comprehensible. Therefore, scaling methods can be used to "distill" the information and re-express its most essential components in a more useable form. In so doing, the resultant scale often produces a summary measure that is superior to any of the constituent variables that comprise it. This occurs because the strengths of one item in the scale can compensate for the weaknesses of another. Thus, the effects of measurement error are minimized.

For example, a public opinion survey might ask its respondents several questions about their feelings toward the incumbent president. The responses to these questions could then be combined into a single scale of attitudes toward the president. The motivations for doing so are that (a) a single variable is easier to analyze than several variables, and (b) the scale would presumably provide a more accurate representation of each respondents' feelings about the president than would any of the individual questions.

DIMENSIONALITY

Second, scaling methods can be used to assess the dimensionality of data. From a substantive perspective, "dimensionality" refers to the number of separate and interesting sources of variation that exist among the objects under investigation. From an analytic perspective, dimensionality refers to the number of coordinates that are required to provide an accurate map of the geometric elements (again, usually points or vectors) used to represent those objects. Again, all scaling procedures seek to represent objects within a space. The dimensions of the space correspond to the sources of variability underlying the objects.

Sometimes, the sources of variability among objects are known beforehand. Therefore, the researcher can specify the dimensionality of the space before the task of locating the object points is begun. This is the case for physical measurement as well as for any other context where objects are compared to each other on the basis of predetermined criteria. For example, an arithmetic test can be viewed as a scaling analysis that seeks to locate a set of objects (students) along a single dimension (corresponding to mathematical skill).

In other situations, scaling procedures are intended to *identify* the number of dimensions that are required. This is particularly important in the social and behavioral sciences, because researchers often do not have a priori knowledge about the underlying sources of variation in their observations. For example, can the various political systems of the world be readily differentiated according to a single continuum that separates democratic from authoritarian systems? Or, would doing so oversimplify a more complex set of distinctions between the sociopolitical structures that actually exist in the world?

In a scaling analysis, dimensionality is assessed by examining the goodness of fit for a particular scaling solution. The actual fit measures differ across the various techniques. For example, with a summated rating scale, the RELIABILITY COEFFICIENT is used to assess the fit. In factor analysis, the sum of the EIGENVALUES or communalities can be used as an overall fit measure. In nonmetric multidimensional scaling, fit is assessed by the stress coefficient. Regardless of the precise details, goodness of fit usually means the degree to which the original data can be predicted from the components of the abstract model that is constructed by the scaling technique. Dimensionality is usually defined by the scaling solution with the smallest number of dimensions that still exhibits an adequate fit to the data.

MEASUREMENT

The third reason for employing scaling methods is measurement. From a substantive perspective, this means obtaining numerical estimates of the relative positions of the objects along the relevant dimensions of variability. In terms of the scaling model, measurement involves finding the coordinates for the scaled objects (again, points or vectors) within the geometric space recovered by the scaling procedure. Once this is accomplished, the numeric values (or “scale scores”) can be used as empirical variables for subsequent analyses. When employed in this manner, scaling methods provide operational representations of phenomena that are inherently unobservable.

For example, summed item scores for responses to a set of survey questions about the president create a Likert scale that serves to measure the respondents’ attitudes toward the president. Alternatively, an MDS analysis might require subjects to assess the similarities among a set of occupations. In the resultant MDS solution, the coordinates of the points could be

interpreted as the occupations’ positions with respect to the various cognitive criteria that the subjects used to evaluate the occupational similarities. In still another application, a researcher might factor analyze data on state governments’ spending across a specified set of public policies. Factor scores could be calculated for the states and interpreted as the priorities that the respective states assign to the policy areas corresponding to the different factors. In every case, the critical point is that the scale(s) produced by the analysis is assumed to provide better measurement of the phenomenon under investigation than any of the original variables.

When scaling solutions are used for measurement purposes, there are several issues that should be confronted. For one thing, the researcher must confirm the VALIDITY of the scale scores as empirical representations of the property that he or she intends to measure. This is a thorny problem, precisely because scales are often employed to measure unobservable phenomena; hence, determining the consistency between the two can be quite difficult. The usual approach is to examine the scale relative to separate, external criteria—either alternative measures of the same property or other variables with theoretically predictable relationships to the property that the scale is measuring. If the scale scores show an appropriate pattern of empirical correlations with other variables, then it is strong evidence in favor of the researcher’s interpretation. If the predicted relationships do not occur, then the scale may be confounding some alternative source of variation in the data, apart from the property that the analyst is trying to measure.

Another problem with some scaling strategies is that the scaling solution is consistent with a sizable (and often infinite) number of different dimensional arrays of the objects under investigation. The final results of a factor analysis or multidimensional scaling analysis locate vectors or points (respectively) within a space of specified dimensionality. However, the orientations of the coordinate axes that define the space are usually arbitrary. If the vectors or points are held at rigid positions with respect to each other, then the axes can be rotated around the configuration to any other location. Of course, changing the orientation of an axis also changes the vector/point coordinates on that axis. This is problematic if the latter are interpreted in substantive terms because the values of the scale scores would change accordingly. With most scaling procedures, there is no way around this problem. Therefore,

the researcher must justify the final scaling solution in terms of factors that are separate from the scaling technique itself (e.g., parsimonious interpretation, fidelity to substantive theory, consistency with external criteria).

GRAPHICAL PRESENTATION

The fourth reason for performing a scaling analysis concerns the presentation of the final results: Because scaling methods seek to produce geometric models of data within a low-dimensional space, it is often possible to construct a graphical depiction of the resultant scaling solution. For example, factor analysis produces a space (hopefully, with few dimensions) containing vectors that represent the common variation within the variables being factor analyzed. Similarly, multidimensional scaling produces a point configuration such that the distances between points correspond to measured dissimilarities between the objects contained in the input data matrix. But even inherently unidimensional methods (e.g., Likert or Guttman scales) can be shown graphically. One of the reasons for using such methods is that the scale provides more detailed resolution of the property being investigated than do the individual items. Hence, a histogram of the scale scores provides far more information about the distribution of objects with respect to the relevant property than would a histogram of scores on any individual item.

The graphical displays obtained from most scaling analyses are very useful for teasing out the substantive implications of the analysis. Interpretation is a creative act on the part of the researcher, accomplished by searching for meaningful systematic structures within the geometric model created by the scaling technique. It is often convenient to do this through visual inspection of the results, because patterned regularities are usually discerned more easily in graphical, rather than numeric, information.

CONCLUSIONS

In summary, scaling methodology provides strategies for modeling systematic structure that exists within a data matrix. Such methods are particularly appropriate when the structure is believed to be due to the existence of latent, or unobservable, sources of variation in the data. The latter feature is precisely what makes scaling so important to the social and behavioral sciences: The central concepts in substantive theories

are inherently unobservable; scaling methods provide tools for operationalization. However, scales only produce models, which are never “right” or “wrong.” They merely represent the analyst’s theory about the nature of the processes that generated the empirical observations. Scaling analyses can generate theory-relevant insights and useful empirical variables. But like any other theory, they remain tentative statements about the nature of reality, subject to challenge if a different scaling model generates an equally parsimonious, interpretable, and analytically useful geometric representation of the same data.

SCATTERPLOT

A scatterplot is a two-dimensional coordinate graph showing the RELATIONSHIP between two QUANTITATIVE VARIABLES, with each observation in a data set plotted as a point in the graph. Although they are employed less frequently in publications than some other statistical graphs, scatterplots are arguably the most important graphs for data analysis. Scatterplots are used not only to graph variables directly, but also to examine derived quantities, such as RESIDUALS from a REGRESSION MODEL.

Precursors to scatterplots date at least to the 17th century, such as Pierre de Fermat’s and René Descartes’s development of the coordinate plane, and Galileo Galilei’s studies of motion. The first statistical use of scatterplots is probably from Sir Francis Galton in the 19th century, and is closely tied to his pioneering work on CORRELATION, regression, and the bivariate-NORMAL DISTRIBUTION.

Several versions of an illustrative scatterplot in Figure 1 show the relationship between fertility and contraceptive use in 50 developing countries. The total fertility rate is the number of expected live births to

Figure 1 Four Versions of a Scatterplot of the Total Fertility Rate (Number of Expected Births per Woman) Versus the Percentage of Contraceptors Among Married Women of Childbearing Age, for 50 Developing Nations

SOURCE: Robey, Rutstein, and Morris (1992).

a woman surviving her child-bearing years at current age-specific levels of fertility. As is conventional, the explanatory variable (contraceptive use) appears on the horizontal axis, and the response variable (fertility) on the vertical axis.

- A traditional scatterplot is shown in Panel A.
- In Panel B, the names of the countries are graphed in place of points. The names are drawn at random angles to minimize overplotting, but many are still hard to read; if the graph were enlarged without

proportionally enlarging the plotted text, this problem would be decreased.

- Panel C displays a more modern version of the scatterplot: Grid lines are suppressed; tick marks do not project into the graph; the data are plotted as open, rather than filled, circles to make it easier to discern partially overplotted points; and the axes are drawn just to enclose the data. The solid curve in the graph represents a ROBUST NONPARAMETRIC REGRESSION smooth; the two broken curves are smoothes based on the positive and negative residuals from the nonparametric regression, and are robust estimates of the STANDARD DEVIATION of the residuals in each direction. The relationship between fertility and contraceptive use is nearly LINEAR; the residuals have near-constant spread and appear symmetrically distributed around the regression curve. More information on smoothing scatterplots may be found in Fox (2000).

- Panel D illustrates how the values of a third, categorical variable may be encoded on a scatterplot. Here, region is encoded using discriminable letters. Similar encodings employ different colors or plotting symbols.

Beyond the illustrations in Figure 1, there are a number of important variations on and extensions of the simple BIVARIATE scatterplot: Three-dimensional dynamic scatterplots may be rotated on a computer screen to examine the relationship among three variables; scatterplot matrices show all pairwise marginal relationships among a set of variables; and interactive statistical graphics permit the identification of points on a scatterplot, and the linking of scatterplots to one another and to other graphical displays. These and other strategies are discussed in Cleveland (1993) and Jacoby (1997).

SCHEFFÉ'S TEST

Henry Scheffé (1953) developed this test to determine which means or combination of means differed significantly from which other means or combination of means in an ANALYSIS OF VARIANCE (in which the scores of the groups are unrelated) when the overall *F* RATIO for those means in that analysis was significant and when such differences had not been predicted prior to the analysis. This type of test is more generally known as a *post hoc* or a *posteriori* test, or a multiple comparison test. It takes into account the fact that a significant difference is more likely to occur by chance the more comparisons that are made. It is suitable for groups of unequal size. Compared to other post hoc tests, it tends to be more conservative in the sense that a significant difference is less likely to be obtained by chance (Toothaker, 1991).

In an analysis of variance, a significant *F* ratio for a factor of more than two groups or for an interaction between two or more factors shows that the variances between the groups differ significantly from the variance expected by chance but does not show which means or combination of means differ significantly. If there were strong grounds for predicting particular differences, the statistical significance of these differences could be determined with an a priori test, such as a one-tailed unrelated *T*-TEST. If there were no strong grounds for predicting particular differences, the number of possible comparisons that can be made is generally greater. For example, the number of means that can be compared two at a time can be calculated with the following formula: $[J \times (J - 1)]/2$, where *J* represents the number of means. So, with 4 means, the number of possible pairwise comparisons is $6 - [4 \times (4 - 1)]/2 = 6$. If the probability of finding a significant difference is set at the usual 0.05 level, the probability of finding one or more of these pairwise comparisons significant at this level can be worked out with the following formula: $1 - (1 - 0.05)^J$. This probability level is known as the familywise error rate, and for 4 comparisons, it is about $0.17 - [1 - (1 - 0.05)^4] = 0.17$. However, there are a number of other comparisons that can be made apart from the pairwise ones that

increase the overall number of potential comparisons. For example, the means of the first two groups can be combined and compared with that of the third or fourth group or the third and fourth groups combined.

The Scheffé test controls for the familywise error rate for more than pairwise comparisons by multiplying the critical value of the F ratio for a factor or interaction by 1 less than the number of groups to be compared. For 4 groups, with 5 cases in each, the .05 critical value of the F ratio is about 3.24, as the degrees of freedom are 3 for the numerator and 16 for the denominator. Consequently, the critical value of the F ratio for the Scheffé test for any comparison of the means of these 4 groups is about 9.72 ($3 \times 3.24 = 9.72$). If the F ratio for the analysis of variance is statistically significant, then at least one of the comparisons of the means must also be statistically significant.

SCREE PLOT

Raymond Cattell (1966) developed the scree test as an alternative to methods such as the Kaiser-Guttman test for determining the number of factors in a FACTOR ANALYSIS that explain a nontrivial amount of the variance that is shared between or common to the variables. It is the first point at which the amount of variance explained by a factor appears to be very similar to that explained by subsequent factors, and it generally tends to be small, suggesting that these factors can be ignored. Scree is a geological term for the rubble and boulders that lie at the base of a steep slope and obscure the real base of the slope itself. In this sense, the test is used to determine which factors can be considered as scree or debris and which do not contribute substantially to any underlying structure of the variables.

In the scree test, the amount of the variance that is accounted for by the factors is plotted on a graph such as that shown in Figure 1. The vertical axis of the graph represents the amount of variance accounted for by a factor. The horizontal axis shows the number of the factor arranged in order of decreasing size of amount of variance, which is the order in which they emerge. The

Figure 1 A Scree Plot

amount of variance explained by a factor is often called the *eigenvalue* or *latent root*. The eigenvalue is the sum of the squared loading or correlation of each variable with that factor. Figure 1 shows the EIGENVALUES of a principal components analysis of 13 variables, which results in 13 factors or components. The scree appears to begin at component number 3. In other words, this test suggests that 2 of the 13 factors should be retained. The point at which the scree begins may be determined by drawing a straight line through or very close to the points represented by the scree, as shown in Figure 1. The factors above the first line represent the number of factors to be retained.

A factor or principal components analysis will always give as many factors or components as there are variables. However, the aim of factor analysis is to determine whether the variables can be grouped together into a smaller number of aggregated or super variables called *factors*. The first factor will always explain the greatest amount of variance between the factors. Subsequent factors will explain decreasing amounts of variance. A criterion needs to be established to determine how many of the subsequent factors can be ignored because they explain too little variance. The Kaiser-Guttman test decrees that factors with eigenvalues of 1 or less should be ignored because these factors explain, at most, no more than the variance of a single variable. In Cattell's experience, this criterion resulted in too few factors with few variables and too many factors with many variables, although he did not specify to what numbers these adjectives referred. Zwick and Velicer (1986) suggest that with 36 and

72 variables, this criterion overestimated the number of factors to a greater extent than did the scree test.

SECONDARY ANALYSIS OF QUALITATIVE DATA

Also called *qualitative secondary analysis*, secondary analysis of qualitative data is the reexamination of one or more existing qualitatively derived data sets in order to pursue research questions that are distinct from those of the original inquiries. Because qualitative inquiries often involve intensive data collection using methods such as SEMISTRUCTURED INTERVIEWS, PARTICIPANT OBSERVATION, and FIELDWORK approaches, they typically create data sets that contain a wealth of information beyond that which can be included in a primary research report. Furthermore, with the fullness of time, new questions often arise for which existing data sets may be an efficient and appropriate source of grounded knowledge.

Secondary analysis also provides a mechanism by which researchers working in similar fields can combine data sets in order to answer questions of a comparative nature or to examine themes whose meaning is obscured in the context of smaller samples. When data sets from different populations, geographical locations, periods of time, or situational contexts are subjected to a secondary inquiry, it becomes possible to more accurately represent a phenomenon of interest in a manner that accounts for the implications of the original inquiry approaches. For example, Angst and Deatrick (1996) were able to draw our attention to discrepancies between chronically ill children's involvement in everyday as opposed to major treatment decisions by conducting a comparative secondary analysis on data sets from their respective prior studies of children living with cystic fibrosis and those about to undergo surgery for scoliosis.

Although QUALITATIVE RESEARCHERS have often created multiple reports on the basis of a single data set,

the articulation of secondary analysis as a distinctive qualitative research approach is a relatively recent phenomenon (Heaton, 1998). Methodological precision and transparency are critically important to the epistemological coherence and credibility of a secondary analysis in order to account for the implications of the theoretical and methodological frame of reference by which the qualitative researcher entered primary study (Thorne, 1994). Regardless of the number of data sets and the level of involvement the secondary researcher may have had in creating them, a secondary analysis inherently involves distinct approaches to conceptualizing sampling, data collection procedures, and interaction between data collection and analysis (Hinds, Vogel, & Clarke-Steffen, 1997).

Qualitative secondary analysis can be an efficient and effective way to pose questions that extend beyond the scope of any individual research team, examine phenomena that would not have been considered relevant at the original time of inquiry, or explore themes whose theoretical potential emerges only when researchers within a field of study examine each others' findings.

SECONDARY ANALYSIS OF QUANTITATIVE DATA

Secondary analysis refers to the analysis of DATA originally collected by another researcher, often for a different purpose. This article focuses specifically on secondary analysis of QUANTITATIVE data, primarily from SURVEYS and CENSUSES. Various definitions, as well as the range of data sources that may be candidates for secondary analysis, are discussed by Hyman

(1972), Hakim (1982), and Dale, Arber, and Procter (1988).

Secondary analysis of high-quality data sets can provide an extremely cost-effective means by which researchers, often with only limited funding, can reap the benefits of a large investment for very little additional cost. The time-consuming and expensive processes of planning and conducting a survey, and cleaning and documenting the data are avoided entirely. However, because the data have been collected by another researcher, the secondary analyst will have had no opportunity to influence the questions asked or the CODING FRAMES used, and this important factor must be borne in mind at all stages of analysis.

HISTORICAL DEVELOPMENT

Secondary analysis of quantitative data became possible with the development of the computer in the 1950s and 1960s. Computerization meant that data could be stored in a form that was compact and readily transportable, and, of great importance, the data could be anonymized so that they could be used by others without revealing identification. The development of computer packages such as SPSS for statistical analysis opened the way for easier and more sophisticated analysis of survey data by many more people than had ever before been possible.

As a response to these developments, DATA ARCHIVES were established for the deposition, cataloging, storage, and dissemination of machine-readable data. During the 1960s, archives were established in the United States (Roper Public Opinion Research Center and the Inter-university Consortium for Political and Social Research, University of Michigan); Europe; and the United Kingdom (UK Data Archives, University of Essex). Since this time, the number of users, as well as the number of studies deposited, has expanded steadily. Also, the type of data has broadened in scope to include administrative records and aggregate data such as area-level statistics from censuses.

APPLICATION

In both Britain and the United States, the availability of large-scale government surveys has been an additional factor of considerable importance in the development of secondary analysis. Government surveys provide data with particular features that are very difficult to obtain through other routes. They are usually nationally representative; with large sample

sizes; conducted by personal interview; and, of great importance, carried out by permanent staff with considerable expertise in SAMPLING, questionnaire design, FIELDWORK, and all other aspects of survey work. The net result is that these surveys provide data of a range and quality that are well beyond the funding that can be obtained by most academic researchers. Secondary analysis has specific value in the following areas.

National-Level Generalizations Across a Wide Range of Topics

Secondary analysis can provide the basis for making generalizations to the POPULATION as a whole. Large government surveys are particularly important because they often cover a wide range of topics in considerable depth and have large enough sample numbers to provide estimates with a high level of accuracy.

Historical Comparisons

Secondary analysis may be the only means by which historical comparisons can be made, particularly where information cannot be collected retrospectively—for example, income and expenditure, or attitudes. Data archives allow the researcher to go back in time and find sources of information on what people thought, how they voted, and how much they earned, perhaps 20 years ago. Many government surveys began in the early 1970s or before, and support analyses of change over time in, for example, women's economic role within the family over a 20-year period.

Longitudinal Analysis

The value of LONGITUDINAL data in testing HYPOTHESES and establishing CAUSAL processes is increasingly recognized. However, the difficulties of establishing and maintaining a longitudinal study for more than a few years are such that secondary analysis is, for most researchers, the only option. In Britain, many longitudinal studies—for example, the British Household Panel Survey—are specifically designed as national resources. In the United States, longitudinal studies such as the Panel Study of Income Dynamics and the National Longitudinal Study of Youth provide similarly rich resources for academic research.

International Comparisons

International comparisons are of great research importance but pose enormous problems of cost and organization and provide another example where secondary analysis plays a vital role. Sometimes, it is

possible to locate data sources from different countries with sufficient similarity in the topics and questions asked to support comparative research—for example, the social mobility studies between England, France, and Sweden (Erikson, Goldthorpe, & Portocarero, 1979). In other cases, surveys are *designed* to allow international comparisons—for example, the European Social Survey, which is designed to chart and explain the interaction between Europe's changing institutions and the attitudes, beliefs, and behavior patterns of its populations.

Representative Data on Small Groups

Secondary analysis can also provide a means of obtaining data on small groups for whom there is no obvious SAMPLING FRAME. Many population surveys will have a sufficiently large sample to support the analysis of relatively small subgroups. For example, a study of the elderly would require considerable screening in order to locate an appropriate sample but can be readily conducted by secondary analysis. Samples of microdata from censuses are typically large enough to support analyses of minority ethnic groups (Dale, Fieldhouse, & Holdsworth, 2000).

Contextual Data for a Qualitative Study

It is often valuable to incorporate a nationally representative dimension into a QUALITATIVE study in order to establish the size and distribution of the phenomenon under study. For example, a qualitative study concerned with expenditure decisions by single parents might be considerably enhanced by including background information that located single parents and their level of income and expenditure within the population as a whole. Often, this kind of contextual information can be obtained cheaply and fairly easily through secondary analysis, in circumstances where the cost of a nationally representative survey would be out of the question. The use of secondary analysis to identify the social and demographic characteristics of the group of interest may also be helpful to qualitative researchers when selecting their sample.

Conversely, secondary analysis can highlight interesting relationships that need to be pursued using qualitative methods.

Confidentiality of Data

Although CONFIDENTIALITY of data is a fundamental consideration in all social research, it is particularly

important when data collected for a specific purpose are made available for analysis by others. Standard precautions are always taken to ensure that individuals cannot be identified, including anonymizing the data by ensuring that name and address are not attached, restricting the geographical area to a level that will not allow identification, and suppressing any peculiar or unusual characteristics that would allow a respondent to be uniquely identified.

SECONDARY ANALYSIS OF SURVEY DATA

Secondary analysis of survey data is the reanalysis of existing survey responses with research questions that differ from those of the original research. With an increasing number of data sets available to researchers, the role of surveys in social research has expanded, and, with improved data quality and access, secondary analysis has assumed an increasingly central position. Secondary survey data are available on a wide range of topics covering health, attitudes, population characteristics, criminal behavior, aging, and more, and many existing data sets are useful for both cross-sectional and temporal analyses. A major advantage of secondary survey analysis is resource economy. Both time and money are saved, and the need for extensive personnel is eliminated. Because the data already exist, the analysis is typically noninvasive, although discussions regarding human subjects implications are ongoing. The availability of multiple data sets simplifies comparative analyses—most often of nations or over time.

The limitations of this method are usually those of VALIDITY, relating to the appropriateness of existing

data for particular research questions. Because the secondary researcher did not design the original survey, it is unlikely that the data set will contain all variables of interest. Even those that do appear may have been measured in ways that diminish their utility. With existing data sets, researchers must be certain that samples represent the population of interest or have enough cases of the needed subpopulation that can be easily extracted. The UNIT OF ANALYSIS must also be compatible with the study. Although many existing data sets were developed with a specific focus, there has been some effort to promote omnibus surveys, that is, those covering a wide range of topics. The most widely known of these is the General Social Survey, which is conducted by the National Opinion Research Center (NORC) at the University of Chicago and contains an array of social indicator data.

Secondary survey data are now widely available on disk, CD-ROM, and the Internet. Many data repositories exist—some with a huge number of holdings covering a variety of topics, and others that are smaller and more specialized. Although academic archives, government agencies, and public opinion research centers (such as Roper and Gallup) are obvious sources of secondary survey data, any organization that stores such data (e.g., private research firms, foundations, and charitable organizations) can be considered a resource for the secondary analyst. A leading data source for academic social science researchers is the Inter-university Consortium for Political and Social Research (ICPSR) at the University of Michigan, which can be accessed on the Internet at <http://www.icpsr.umich.edu>. The ICPSR is an excellent starting point for locating desired data. In addition to their substantial holdings, the Web site provides links to other archives.

To make the best use of existing survey data, researchers should merge general substantive interests with familiarity of existing data and be able to evaluate primary data source(s) with respect to survey design and administration, issues of sampling, and data set limitations. Furthermore, researchers must be creative in their approach to combining data both within and across surveys, and by incorporating data from outside the data set. Although inherent challenges persist in the use of existing survey data, the opportunities for social research are enormous.

—Laura Nathan

SECONDARY DATA

Analysts may gather DATA themselves by carrying out a SURVEY, doing an EXPERIMENT, CONTENT ANALYZING newspapers, or CODING observed behaviors, to name a few methods, all of which generate primary data. In contrast, secondary data are data gathered by someone other than the analyst. A great deal of social science work is done on secondary data. For example, a social researcher may go to the library and gather together data first assembled by the U.S. Census Bureau. Or, a psychologist may collect data on a number of published experiments testing a particular hypothesis, in order to carry out a META-ANALYSIS of those studies. Another example is the use of data archived in data banks, such as the Inter-university Consortium for Political and Social Research. Increasingly, secondary data are available on the Web. Secondary data have the advantage that they are much less costly than primary data because you do not have to gather them yourself. They have the disadvantage that they may not contain the particular OBSERVATIONS or VARIABLES that you would have included if you had directed the study. Increasingly, general social surveys (such as the General Social Survey) are conducted without a particular primary research goal for each collection, but instead to facilitate researchers using them as what might be called “secondary” primary data.

—Michael S. Lewis-Beck

SECOND-ORDER. See ORDER

SEEMINGLY UNRELATED REGRESSION

Seemingly Unrelated Regression or Seemingly Unrelated Regression Equations (SURE) is a method used when two or more separate REGRESSION equations that have different sets of INDEPENDENT VARIABLES are related to each other through correlated DISTURBANCE TERMS. Estimation with SURE produces more efficient coefficients than estimation with separate regressions, especially when the disturbances are highly correlated and the sets of independent variables are not highly

correlated. The SURE estimation method can be applied to pooled TIME-SERIES CROSS-SECTION data that are either time-series dominant or cross-section dominant. It can also be applied to CROSS-SECTIONAL DATA and to TIME-SERIES DATA. If the error terms of the equations are not correlated, then ORDINARY LEAST SQUARES (OLS) REGRESSION can be used on each equation separately.

A model of federal agency budgets illustrates the SURE method. If the DEPENDENT VARIABLE is spending levels for federal agencies, and if separate models are estimated for different types of agencies, then the disturbance terms of the separate models are likely to be correlated. That is, the spending levels for the different types of agencies are all likely to be influenced by common exogenous shocks. For example, the U.S. war on terrorism produces large demands on the budget that influence the spending levels of various nondefense agencies.

SURE is also best applied when each equation in the set of equations has a different set of independent variables. In the budget example, this allows the researcher to recognize that not all agencies are alike and to group the agencies by type in different models. Grouping agencies by type and putting them into separate equations allows for agencies to be influenced differently by the same independent variables and also to be influenced by different independent variables. For example, unemployment may influence regulatory agency budgets like the Nuclear Regulatory Agency differently from how it influences the budget for the Employment and Training Administration under the Department of Labor. And unemployment may have no influence at all on regulatory agencies like the Federal Communications Commission, which means it should not be in the model for regulatory agencies. In contrast, OLS or GENERALIZED LEAST SQUARES (GLS) estimation of pooled agency data assumes that all of the agencies are influenced the same way by the same independent variables. That is, not only are the data pooled together, but the estimates are also pooled together.

SELECTION BIAS

Selection bias is an important concern in any social science research design because its presence generally leads to inaccurate estimates. Selection bias occurs when the presence of observations in the SAMPLE depends on the value of the variable of interest. When this happens, the sample is no longer randomly drawn from the population being studied, and any inferences about that population that are based on the selected sample will be biased. Although researchers should take care to design studies in ways that mitigate nonrandom selection, in many cases, the problem is unavoidable, particularly if the data-generating process is out of their control. For this reason, then, many methods have been developed that attempt to correct for the problems associated with selection bias. In general, these approaches involve modeling the selection process and then controlling for it when evaluating the outcome variable.

For an example of the consequences of selection on INFERENCE, consider the effect of SAT scores on college grades. Under the assumption that higher SAT scores are related to success in college, one would expect to find a strong and positive relationship between the two among students admitted to a top university. The students with lower SAT scores who are admitted, however, must have had some other strong qualities to gain admittance. Therefore, these students will achieve unusually high grades compared to other students with similar SAT scores who were not admitted. This will bias the estimated effect of SAT scores on grades toward zero. Note that the selection bias does not occur because the sample is overrepresentative of students with high SAT scores, but because the students with low scores are not representative of all students with low SAT scores in that they score high on some unmeasured component that is associated with success.

A frequent misperception of selection bias is that it can be dismissed as a concern if one is merely trying to make inferences about the sample being analyzed rather than the population of interest, which would be akin to claiming that we have correctly estimated the

relationship between SAT scores and grades among admittees only. This is false: The grades of the students in our example are representative of neither all college applicants nor students with similar SAT scores. Put another way, our sample is not a random sample of students conditional on their SAT scores. The estimated relationship is therefore inaccurate. In this example, the regression coefficient will be biased toward zero because of the selection process. In general, however, it may be biased in either direction, and in more complicated (multivariable) regressions, the direction of the bias may not be known.

Although selection bias can take many different forms, it is generally separated into two different types: CENSORING and TRUNCATION. Censoring occurs when all of the characteristics of each observation are observed, but the dependent variable of interest is missing. Truncation occurs when the characteristics of individuals that would be censored are also not observed; all observations are either complete or completely missing. In general, censoring is easier to deal with because data exist that can be used to directly estimate the selection process. Models with truncation rely more on assumptions about how the selection process is related to the process affecting the outcome variable.

The most well-known model for self-selectivity is James Heckman's ESTIMATOR for a continuous dependent variable of interest that suffers from censoring (Heckman, 1979). This estimator corrects for selection bias in the linear regression context and has been widely used in the social sciences. Heckman's correction attempts to eliminate selection bias by modeling the selection process using a PROBIT equation where the dependent variable is an indicator for whether or not the observation is censored. It then estimates the conditional expected value of the error term in the equation of interest, which is not zero if it is correlated with the error in the selection equation. This variable, known as the inverse Mills' ratio, is then included as an additional regressor in the equation of interest, which is estimated using OLS. The standard errors need to be adjusted if the model is estimated this way because they understate the uncertainty in the model. Alternatively, both equations can be estimated simultaneously using maximum likelihood techniques, and no adjustment is needed. When its assumptions are met, Heckman's estimator provides unbiased, consistent estimates and

also provides an estimate of the correlation between the two error terms.

The presence of selection bias can be tested for in the Heckman model by conducting a significance test on the coefficient for the selection term or, more generally, by conducting a LIKELIHOOD RATIO TEST for the fit of the selection model relative to the uncorrected model. Care must be taken in interpreting the effects of independent variables on the dependent variable of interest because some will influence it indirectly through the selection equation as well as directly in the equation of interest. Another important consideration is the presence of factors that influence that selection equation that do not directly influence the quantity of interest. Although the model is identified (by functional form alone) without such factors, the inclusion of factors that belong in the selection equation but not the equation of interest will generally improve the reliability of the model because they increase the variation of the inverse Mills' ratio.

More advanced techniques have been developed for more complicated settings, including those where the data are truncated, which makes it impossible to directly estimate a selection equation, and those where the dependent variable of interest is binary rather than continuous (Dubin & Rivers, 1989). For an overview of these methods, see Maddala (1983); for more advanced approaches, including semiparametric methods that relax distributional assumptions, see Winship and Mare (1992). In general, the more advanced methods have been developed in response to findings that standard selection bias models are often sensitive to the assumptions of the correction, particularly that the two error terms are distributed bivariate normal.

SELF-ADMINISTERED QUESTIONNAIRE

Self-administered QUESTIONNAIRES are one of the most frequently used methods for collecting DATA for research studies. Furthermore, self-administered questionnaires appear in many areas of our lives. Think, for example, of the testing strategies used in most classrooms from kindergarten through graduate school. Classroom tests are a type of self-administered questionnaire. Similarly, we fill out forms or questionnaires to obtain everything from a driver's license to a death certificate.

The very proliferation and familiarity of self-administered questionnaires in a wide variety of daily life settings often results in people assuming that they can develop a questionnaire literally overnight and use it to collect data immediately. But, like any research endeavor, the development of self-administered questionnaires takes time and thought if the researcher wants to maximize the collection of complete, reliable, and valid data.

TYPES OF SELF-ADMINISTERED QUESTIONNAIRES

Questionnaires can be completed in either supervised or unsupervised settings. In supervised settings, someone is available to answer questions that respondents might have, monitor whether respondents talk with each other while filling out the questionnaire, and encourage respondents to complete the questionnaire and return it to the researcher or other personnel. Passing out questionnaires in a classroom is an example of a supervised group administration. Questionnaires may also be given to individuals to fill out in less structured settings such as registration lines, where a data collector is available but less obvious.

Questionnaires that are mailed to respondents are the most common example of unsupervised administration, but increasingly, questionnaires are being administered through e-mail, the Internet, and other ONLINE METHODS. Self-administered questionnaires used in all settings must stand alone, or be completely self-explanatory, but this is particularly important when unsupervised administrative procedures are used.

ADVANTAGES AND DISADVANTAGES

The single greatest advantage of self-administered questionnaires is their lower cost compared to other data collection methods. MAIL QUESTIONNAIRES have three sample-related advantages—wider geographic coverage, larger samples, and wider coverage within a sample population—and all self-administered questionnaires are easier to implement because fewer personnel are needed for data collection, processing, and analysis. Unlike most other methods of data collection, it can be assumed that when a questionnaire is sent through the mail or distributed online, all members of the sample receive it nearly simultaneously. Many researchers believe that more complete and truthful information on SENSITIVE TOPICS is obtained with self-administered questionnaires.

Mail and self-administered questionnaires have a number of disadvantages that limit or prohibit their use in many research settings. Address lists must be available if mail or online administration is to be used. One of the biggest and most studied disadvantages of mail questionnaires is the low response rate. When no effort is made to follow up the original mailing with additional mailings or phone contacts, the expected response rate in a general community sample is around 20%. To date, online survey response rates appear to be even lower. Self-administered questionnaires cannot be used with the estimated 20% of the population that is functionally illiterate, or with populations that include substantial proportions of respondents who do not read the language in which the research is being conducted. Elderly people or other groups with visual problems may also find it difficult or impossible to fill out questionnaires.

Self-administered questionnaires can be used only when the objective of the study is clear and not complex. The need for a clear and noncomplex data collection objective has ramifications for how the questionnaire is constructed and precludes the use of many strategies typically used in designing questionnaires used in interviews. First, questionnaires must be shorter and, hence, the number of questions asked and the amount of data collected are reduced. In general, the upper limit for a self-administered questionnaire is thought to be 12 pages, but length varies with respondent motivation. When a topic is particularly important to respondents, they will tolerate a longer questionnaire. Second, the questions must be CLOSED-ENDED. Although highly motivated respondents may

be willing to answer a few OPEN-ENDED QUESTIONS, the researcher who develops a questionnaire dominated by open-ended questions will find that few questionnaires will be completed and returned, and that those that are returned will have substantial amounts of MISSING or irrelevant data. Third, the questionnaire must stand alone. In other words, all the information that the potential respondent needs to answer the questions must be provided on the questionnaire itself because there is no interviewer available to clarify instructions or provide additional information. Fourth, in simplifying the task for respondents, the surveyor cannot use branches or skips. Every question should contain a response category that each respondent can comfortably use to describe his or her attitudes, behavior, knowledge, or characteristics. In some instances, this means that a “not applicable” alternative must be included among the responses provided.

The single biggest administrative disadvantage with unsupervised self-administered questionnaires is the fact that once the questionnaire leaves the researcher’s office, he or she has no control over who, in fact, completes it and whether that person consults with others when completing it. Furthermore, the researcher has no control over the order in which questions are answered. As a result, self-administered questionnaires cannot be used when one set of questions is likely to contaminate, BIAS, or influence answers to another set of questions.

DESIGNING SELF-ADMINISTERED QUESTIONNAIRES

Three kinds of information must be evaluated in deciding whether or not data can be collected by mail or other self-administered questionnaire. These are the literacy level and motivation of the targeted population, and whether characteristics of the RESEARCH QUESTION make it amenable to data collection using a self-administered questionnaire. Literacy is usually fairly easily assessed, but motivation is much more difficult to determine. To be amenable to study, the topic must be one that can be reasonably covered in a relatively short and focused questionnaire, with questions that are relevant for everyone in the sample. Self-administered questionnaires generally work best when the focus is in the present, rather than the past or the future. Unsupervised self-administered questionnaires, in particular, cannot be used in exploratory

studies or when the surveyor is in the process of developing a research question and the procedures by which that question will be studied.

It is particularly important for self-administered questionnaires to be user friendly. This is maximized both by the way questions are written and by the way in which questionnaires are formatted. Questions must be short and specific rather than general. This may mean that multiple questions, rather than a single question, must be asked. Response categories must be exhaustive and mutually exclusive. Sometimes, this means that questions should be structured so that respondents can select more than one answer to describe themselves, or that a “residual other” must be included among the response categories for a respondent. “Residual other” categories are particularly important when researchers do not think that they have an exhaustive list of possible answer categories.

One of the biggest errors made in developing questionnaires is to try to make them look shorter with the idea that this will increase response rates and decrease mailing costs. This is often done by squeezing all of the questions onto two pages, leaving little or no space between questions, and by using small type fonts. In fact, such procedures reduce response rates. Forcing questions onto a few pages generally means that the font is small and no space is left between questions. A small font makes it difficult for respondents to read the questionnaire. Judicious use of blank space makes it easier for respondents to see both the questions and the associated response categories, and to expeditiously progress through the questionnaire.

SELF-COMPLETED QUESTIONNAIRE.

See SELF-ADMINISTERED QUESTIONNAIRE

SELF-REPORT MEASURE

Information about individuals may be obtained by direct OBSERVATION or through their reporting on their own behavior or attitudes in a survey. In some circumstances, the researcher may have a choice about which method of observation to use, but in many cases, self-report measures are the only ones that can be used. A researcher could ask individuals to get on a scale in order to measure their weight, or ask them in a SURVEY how much they weigh. In this case, the scale is much more likely to produce the correct value. Another researcher interested in voting behavior could check official records for voting information or could ask respondents in a survey whether or not they voted in the most recent election. Some voting studies use both measures in order to feel more confident about the VALIDITY of the respondents' actual behavior.

The potential problem with self-report measures is that they may contain one or more kinds of SYSTEMATIC ERROR or BIAS. This may derive from the way the question is worded or the response alternatives the respondent is offered, the order in which the questions were asked, the respondent's interaction with the INTERVIEWER, or the respondent's view of "acceptable" answers in this particular social setting.

OPEN-ENDED QUESTIONS, where respondents provide answers in their own words, often provide different responses than do CLOSED-ENDED QUESTIONS, where respondents have to choose from one of the offered responses. Offering an explicit opportunity to say "I don't know" or the alternative of saying "I haven't really thought about that" usually produces a different pattern of responses than not offering such an option. The range of scales and how they differ among questions can also explain differences in the answers respondents give (Schwarz, Hippler, Deutsch, & Strack, 1985).

The order in which questions are asked may lead respondents to an inevitable conclusion by the final item in the series. Asking a series of questions in an Agree/Disagree format may induce RESPONSE SET bias because of the willingness of respondents to agree with attitudinal statements posed to them (Schuman & Presser, 1996).

One of the most important forms of self-report bias is associated with SOCIAL DESIRABILITY BIAS, or the

tendency to offer responses that are felt to be more acceptable than the others. This is the most common explanation for the universally observed propensity of people to say they voted when record checks indicate that many of them did not. Racist attitudes are typically understated for the same reason. These self-report response patterns can be linked to the nature of the relationship between the social characteristics of the respondent and the interviewer, such as race or gender.

SEMANTIC DIFFERENTIAL SCALE

The semantic differential (SD) is a technique developed during the 1940s and 1950s by Charles E. Osgood to MEASURE the meaning of language quantitatively. Words may have different meanings to different individuals as a function of their experiences in the world. For example, "poverty" has been experienced differently by 7- and 70-year-olds, and by the rich and the homeless. Their expressions of understanding of poverty are modified by these experiences. The SD captures these different meanings by providing some precision in how our understanding of words differs.

The typical semantic differential test requires a subject to assess a stimulus word in terms of a series of descriptive bipolar (e.g., good-bad) scales. The subject is asked to rate the stimulus between the extreme and opposing adjectives that define the ends of these scales. Typically, these bipolar scales have 5 or 7 points. The odd number allows the subject to choose a midpoint or neutral point (which would not be available if an even number of options were used). The various scale positions may be unlabeled, numbered, or labeled (see Table 1).

Table 1

Good	[]	[]	[]	[]	[]	Bad
Good	-2	-1	0	1	2	Bad
Good	Very	Quite	Neither	Quite	Very	Bad

Respondents seem to prefer the labeled version.

Typically, a stimulus will be assessed in terms of a large number of these bipolar scales. For example,

Good-Bad	Hard-Soft
Rough-Smooth	Fast-Slow
Fresh-Stale	Noisy-Quiet
Small-Large	Young-Old
Strong-Weak	Tense-Relaxed
Active-Passive	Valuable-Worthless
Cold-Hot	Unfair-Fair
Honest-Dishonest	Empty-Full
Bitter-Sweet	Cruel-Kind

The pattern of responses to these bipolar scales defines the meaning subjects attribute to the stimulus word.

Osgood's early research into the usefulness of the SD suggests that respondents' ratings of stimuli on these BIPOLAR SCALES tend to be correlated. Osgood argues that the semantic space is MULTIDIMENSIONAL but can be represented efficiently by a limited number of orthogonal DIMENSIONS. Three dimensions typically account for much of the covariation found in responses to the individual bipolar scales. These dimensions have been labeled Evaluation, Potency, and Activity (EPA) and have been found in a wide array of diverse studies. One way to interpret this finding is that, although the meanings of the bipolar scales may vary, many are essentially equivalent and hence may be represented by a small number of dimensions. To the extent that meanings are equivalent across groups, space, or time, the similarities and differences of groups, cultures, and epochs may be examined.

In practice, the semantic differential may be used to develop a nuanced understanding of attitudes. For example, Americans often hold ambiguous opinions of their national institutions and political leaders. Yet citizens are often asked their assessment of a political institution or elected official in a single question. One common question used to examine public perceptions of the American president is, "Do you

approve or disapprove of the way [name of current president] is handling his job as president?" Using the SD approach, it is possible to develop a more complex appraisal of public opinion by asking respondents to rate the president on a series of bipolar scales (see Table 2):

Table 2

Please rate George W. Bush on each of the following distinctions:

Good	[]	[]	[]	[]	[]	Bad
Weak	[]	[]	[]	[]	[]	Strong
Active	[]	[]	[]	[]	[]	Passive
Fair	[]	[]	[]	[]	[]	Unfair
Helpful	[]	[]	[]	[]	[]	Unhelpful
Dishonest	[]	[]	[]	[]	[]	Honest
Sharp	[]	[]	[]	[]	[]	Dull
Ineffective	[]	[]	[]	[]	[]	Effective
Fast	[]	[]	[]	[]	[]	Slow
Valuable	[]	[]	[]	[]	[]	Worthless
Powerless	[]	[]	[]	[]	[]	Powerful
Brave	[]	[]	[]	[]	[]	Cowardly

Responses to each scale may be examined individually, or they may be subject to data reduction (e.g., FACTOR ANALYSIS) to explore public assessments of the president on the EPA dimensions.

The SD has found wide use in sociology, communication studies, cognitive psychology, and marketing research.

Critics have identified one logical pitfall in the SD approach to measuring attitudes: Research based on the semantic differential begins with the assumption that people hold different attitudes/perceptions of a stimulus item—a word. But the SD technique assumes that adjectives chosen to represent the ends of the bipolar scales mean the same thing to each rater.

SEMILOGARITHMIC. See LOGARITHMS

SEMIOTICS

Broadly defined, *semiotics* is the theory of meaning, the scientific domain that studies the structure and function of systems of signification and communication, and of the signifying (meaningful) wholes constructed from them. The term *semiotics* derives from *semi-otic*, used by one of the two founders of modern semiotics, the American philosopher Charles Sanders Peirce (1839–1914). A competing term is *semiology*, coined by the other founder of semiotics, the Swiss linguist Ferdinand de Saussure (1857–1913). *Semiotics* came to be used universally after a meeting held at Indiana University, Bloomington, in 1964 (although certain semioticians within the Saussurian tradition continue to differentiate between the two terms).

According to this definition, semiotics is not a separate science, but a scientific domain. In fact, the object of semiotics, signifying wholes and systems, is too broad to define a science; indeed, it cuts through a multiplicity of established sciences (e.g., linguistics, anthropology) and disciplines (e.g., literature, architecture, music).

For Saussurian STRUCTURAL LINGUISTICS, Peircian semiotics, and most other semiotic theories, the basic unit of semiotics is the unitary *sign* (although there are some theories that operate with broader signifying entities). A unitary sign is anything whatsoever that can be taken as an entity standing for (signifying) another entity. The word “tree” is a unitary sign, denoting a certain kind of plant (with a trunk, branches, leaves, etc.). Thus, unitary signs are signifying units, consisting in Saussure’s terminology of a *signifier*—the vehicle of signification—and a *signified*—the signification itself. The fact that semiotics studies the relationships between (at least) two planes—the signifier and the signified—differentiates semiotics from *information theory*, which deals only with the plane

of the signifier. Peirce defines the sign in terms of a triadic relational structure involving the *sign*, which is anything that conveys meaning; the *object* for which the sign stands; and the *interpretant*, the idea provoked by the object. The interpretant can itself be named by another sign, bringing about its own interpretant, and so on (theoretically) ad infinitum in a process of “unlimited semiosis.” The most fundamental division of signs for Peirce is into *icons*, *indices*, and *symbols*. Whereas the index and the icon are related to the things they signify pragmatically or through similarity, respectively, the symbol is purely conventional. In this, it resembles the Saussurian sign, which is conventional and arbitrary, that is, there is no natural relation between signs and the things for which they stand, a principle that also holds for the relation between signifier and signified.

Signs in communication are combined into signifying wholes, such as messages, discourses, or TEXTS. A signifying whole is a group of signs, combined according to certain syntactic rules. A building is an example of a signifying whole; a certain kind of building (with pointed arches, towers, and a set of other characteristics) denotes “gothic cathedral,” which in turn may call up connotations of “sacred place” and “transcendence.” This example shows the two levels of signification of a sign: the literal signification, or *denotation*, and the indirect or symbolic signification, *connotation*.

Signifying wholes presuppose systems of signification. Saussure called the system of signification *langue* (usually translated as “the language system” and used in semiotics to refer to any system of signs). The system is *synchronic*, that is, it represents a particular static state of *langue* (as opposed to its *diachronic* changes); it is social in nature, and, for Saussure, it is the privileged point of view for the study of natural language. The term *structure* is often used as equivalent to *system*, although it can also refer to the rules governing the system.

The system is a key concept for Saussurian semiotics. Given the principle of the arbitrariness of the sign, meaning is not considered as deriving from any relationship between signs and the real world, but is the result of the mutual relations between signs within the context of an abstract and purely formal system of an algebraic nature. Signifiers (and signifieds) are constituted through their differences from other signifiers (or signifieds) of the system. The differential nature of signification is one of the founding principles of Saussurian structural linguistics. Ultimately, any

positive content of the signified is denied, because signification follows from the relations of a sign with the other signs of the system, its *value*. Values—and thus the whole system—are determined through the interplay of two kinds of relations between signifiers: *paradigmatic* relations, deriving from the classification of signs in sets (one of Saussure's examples is the set “teaching,” “instruction,” “apprenticeship,” “education”), and *syntagmatic* relations, the result of selecting signs from various paradigms and combining them into the linear syntagms of language (sentences, texts).

Langue is opposed to *parole* (speaking), the use of the language system by individuals. Semiotic systems are used and thus function within society. Their central, although not their only, function is communication. Signifying wholes are constituted on the level of *parole*. *Pragmatics* (in the wide sense) is the branch of semiotics that studies the process of production and functioning of signifying wholes, that is, their use; their cognitive, emotional, or behavioral-corporeal impact on the receiver; and their dynamic interaction with the situation of communication.

HISTORICAL DEVELOPMENT

Although the Greeks and other ancient cultures were concerned with the issue of meaning, modern semiotics has its origins in the works of Peirce and Saussure. In the United States, semiotics gained wider recognition through the work of Charles William Morris, who divided semiotic analysis into *syntactics*, *semantics*, and *pragmatics* (which he defines as the study of the relation between signs and interlocutors). A tendency primarily in the United States to extend semiotics beyond the study of human signifying systems to animal communication (*zoosemiotics*) and further to the natural processes of all living organisms (*biosemiotics*) owes much to the work of Thomas A. Sebeok.

A decisive influence on the formation of European semiotics was the Russian linguist Roman Jakobson. In the second decade of the 20th century, Jakobson, who worked within the Saussurian tradition, participated in the creation of two semiotic groups in Russia that formed the nucleus of Russian Formalism, and in the next decade, he was instrumental in founding the Prague Linguistic Circle, which marked the constitution of European linguistic STRUCTURALISM proper. The work of Jakobson and the Prague Circle envisages natural language as one among a multitude of sign

systems, which together constitute culture as a complex system of communication (a view later continued by the postwar Moscow-Tartu School of semiotics). An important contribution to the development of European semiotics was also made by the Danish linguist Louis Hjelmslev, who cofounded the Linguistic Circle of Copenhagen in 1931.

During World War II, Jakobson met and influenced a French anthropologist, Claude Lévi-Strauss. The structural anthropology of Lévi-Strauss was crucial to the flourishing of semiotics in the 1960s and 1970s. In 1964, the literary scholar Roland Barthes published the first contemporary treatise on semiotics, *Éléments de Sémiologie*, soon followed by major works by other well-known semioticians such as the founder of the Paris School Algirdas Julien Greimas and the Italian philosopher Umberto Eco. At the same time, the tendency that later became known as POSTSTRUCTURALISM developed in Paris; eminent authors are the philosophers Jacques Derrida and François Lyotard, the psychoanalyst Jacques Lacan, the historian of knowledge (of “discourses”) Michel Foucault, and the sociologist Jean Baudrillard.

METHODOLOGY AND APPLICATIONS

Semiotic methodology can be understood by comparison to two of the methods most commonly used today for the analysis of meaning, CONTENT ANALYSIS and the SEMANTIC DIFFERENTIAL. Both of these presuppose the creation of qualitative categories, and both result in quantitative statistical analysis; however, they adopt a rather limited view of the text and lack any substantial theoretical elaboration, drawing their value from their methodological, not to say technical, interest. Contrary to this, semiotic methodology is based on an extremely sophisticated theory, covers all or nearly all of the aspects of a text, and has been established as primarily qualitative.

Conventional methods for the analysis of meaning do not generally address the syntagmatic, or linear, dimension of texts. On the other hand, semiotics disposes of a quite elaborate *narrative* theory formulated largely by A. J. Greimas. Greimas decomposes a text into units of “doing,” integrating units of “state” formed by the conjunction or disjunction between various kinds of subject and object. This elementary narrative program, the act, produces or changes a state, that is, effects the transition from one state to another. The syntagmatic organization of these acts

leads to action. Every discourse—not only narrative discourse—is a process leading from an initial to a final state and can be formally simulated by an ALGORITHM of transformation.

One of the earliest examples of semiotic methodology is offered by Barthes's (1977) paradigmatic analysis of an advertisement by the Italian food manufacturer Panzani. The aim of paradigmatic analysis is comparable to that of content analysis and the semantic differential.

Barthes distinguishes two complementary types of messages in the advertisement, the iconic and the linguistic. In the iconic message, he identifies two levels, the literal or denotative message (i.e., the objects in the image), and the symbolic or connotative message; the linguistic message serves to guide the interpretation of the symbolic. Barthes observes that the literal message as syntagm is the necessary support of the symbolic one, because certain noncontinuous elements of the former lead to the appearance of "strong" signs, bearers of a second-level meaning. He identifies four major meanings of this kind: "return from the market" with the accompanying euphoric values of the freshness of the produce and their domestic use, anchored in the half-open net bag from which the provisions spill; "italicity" (cf. the name "Panzani"), a kind of condensed essence of everything Italian, from spaghetti to painting, derived from the three colors in the image together with the (Mediterranean) vegetables tomato and pepper (green, white and red being the colors of the Italian flag); "complete culinary service," due to the gathering together of many different foodstuffs; and "still life," due to the composition, which is reminiscent of painting. To these four symbolic meanings correspond four paradigmatic codes, which Barthes calls the practical, the national, the cultural, and the aesthetic.

Although semiotic analysis is usually qualitative, it is occasionally combined with a quantitative aspect. A. Ph. Lagopoulos and K. Boklund-Lagopoulou, studying the conception of regional space in four settlements of northern Greece, analyze the content of the interviews they conducted into 32 paradigmatic codes, grouped into eight major sets, characteristic of "discourse on space." They then use frequency counts and cross-tabulations to study a wide set of semiotic (conceptual) variables, including the codes, and their relationship to sociological (social class, gender, age group, education) and sociogeographical (urban vs. rural, settlement hierarchy) variables, as well as relationships between various kinds of semiotic data.

SEMIOTICS TODAY

Today, semiotics has permeated all of the social and human sciences and is an important component of the dominant paradigm of our times, POSTMODERNISM. In linguistics and literary studies, it has contributed to the development of such areas as lexicology; DISCOURSE ANALYSIS (in particular, rhetoric); narratology; and stylistics. It has deeply influenced anthropology and the study of mythology. It has also penetrated semantics and contributed greatly to the study of nonverbal and mixed systems, leading to the creation of, for example, a semiotics of behavior, painting and photography, music, architecture and urban space, culinary habits, the circus, fashion, advertising, cinema, and the theater. Most significantly, semiotics has provided a unified theoretical framework for the comparative study of cultural phenomena, contributing significantly to the present unparalleled flourishing of interdisciplinary and cross-disciplinary studies of signifying structures and practices of all kinds.

—Karin Boklund-Lagopoulos and
Alexandros Lagopoulos

SEMIPARTIAL CORRELATION

A semipartial correlation is a statistic measuring the relationship between a DEPENDENT VARIABLE (or criterion) with an adjusted INDEPENDENT VARIABLE (or predictor) controlling for the effect of other predictors in the analysis. Like PARTIAL CORRELATION, the

Figure 1 Diagrams Illustrating Conceptual Differences Between Semipartial, Partial, and Pearson's Correlations

semipartial correlation is computed in the process of MULTIPLE REGRESSION ANALYSIS.

The diagrams illustrate how the semipartial correlation differs conceptually from both partial and Pearson's correlations. Grey circles (A s and B s) in the diagrams represent predictor variables, whereas the black circles, Y s, represent criterion variables. Boxes represent residuals of A s and Y s after subtracting the effects that the B s exert on them. Curved arrows represent correlation (or COVARIANCE) between pairs of variables in the diagrams, whereas the straight arrow represents a regression path connecting B to Y .

In Figure 1a, the curved arrow r_{YA} represents a zero-order Pearson's correlation coefficient, which measures the extent to which A and Y are correlated with each other, not taking into account the effect of the third variable B . In Figure 1b, the curved arrow $sr_{YA,B}$ represents a semipartial correlation coefficient. It measures the extent to which the criterion, Y , and the RESIDUAL of A (i.e., $d_{A,B}$), obtained by subtracting from A its covariance with B , are correlated with each other. In Figure 1c, the curved arrow $pr_{YA,B}$ represents a partial correlation coefficient. It measures the extent to which the residual of Y (i.e., $d_{Y,B}$) and the residual of A (i.e., $d_{A,B}$) are correlated with each other.

Illustratively, in a multiple regression analysis in which Y is the criterion variable that is predicted by A and B (two predictors), both the semipartial correlation and the partial correlation obtained from A and B would be related to specific (or unique) contributions

of A and B , respectively. In particular, the squared semipartial correlation for A is the proportion of the *total* variance of Y uniquely accounted for by A , after removing the shared variance between A and B from A but not from Y . Alternatively, the squared partial correlation for A is the proportion of the *residual* variance of Y uniquely accounted for by A after removing the effect of B on both A and Y .

Both the partial and semipartial correlations for any given pair of variables can be calculated on the basis of the zero-order Pearson's correlation between a pair of variables according to the following algebraic rules:

$$sr_{YA,B} = \frac{r_{AY} - (r_{AB})(r_{YB})}{\sqrt{1 - r_{AB}^2}} \quad (1)$$

$$pr_{YA,B} = \frac{r_{AY} - (r_{AB})(r_{YB})}{\sqrt{1 - r_{YB}^2} \times \sqrt{1 - r_{AB}^2}} \quad (2)$$

Comparing equations (1) and (2), the computation of a semipartial correlation (i.e., $sr_{YA,B}$) differs from that of a partial correlation (i.e., $pr_{YA,B}$) in the composition of their denominators. The partial correlation equation has a smaller denominator than does the semipartial correlation equation (i.e., for the partial correlation, the denominator is a product of two terms each smaller than 1.00, whereas the semipartial correlation includes only one of those terms). These differences

make a semipartial correlation always lower than a partial correlation, except for the cases where *A* and *B* are independent or uncorrelated.

SEMISTRUCTURED INTERVIEW

Semistructured interviewing is an overarching term used to describe a range of different forms of interviewing most commonly associated with QUALITATIVE RESEARCH. The defining characteristic of semistructured interviews is that they have a flexible and fluid structure, unlike STRUCTURED INTERVIEWS, which contain a structured sequence of questions to be asked in the same way of all interviewees. The structure of a semistructured interview is usually organized around an aide memoire or INTERVIEW GUIDE. This contains topics, themes, or areas to be covered during the course of the interview, rather than a sequenced script of standardized questions. The aim is usually to ensure flexibility in how and in what sequence questions are asked, and in whether and how particular areas might be followed up and developed with different interviewees. This is so that the interview can be shaped by the interviewee's own understandings as well as the researcher's interests, and unexpected themes can emerge.

LOGIC AND UNDERPINNINGS OF SEMISTRUCTURED INTERVIEWING

Semistructured interviewing is most closely associated with INTERPRETIVIST, INTERACTIONIST, CONSTRUCTIONIST, FEMINIST, PSYCHOANALYTIC, and ORAL or LIFE HISTORY traditions in the social sciences. It reflects an ONTOLOGICAL position that is concerned with people's knowledge, understandings, interpretations, experiences, and interactions. Elements of the different traditions can be identified in contemporary semistructured interviewing practice, which Jennifer Mason suggests is broadly characterized by

the interactional exchange of dialogue; a relatively informal style; a thematic, topic-centered, biographical, or narrative approach; and the belief that knowledge is situated and contextual, and that therefore the role of the interview is to ensure that relevant contexts are brought into focus so that situated knowledge can be produced (Mason, 2002, p. 62).

Most commentators agree that the logic of semistructured interviewing is to generate data interactively, and Steinar Kvale has described qualitative research interviews as "a construction site of knowledge" (Kvale, 1996, p. 2). This means that the interviewer, and not just the interviewee, is seen to have an active, REFLEXIVE, and constitutive role in the process of knowledge construction. Data are thus seen to be derived from the interaction between interviewer and interviewee, and it is that interaction, rather than simply the "answers" given by the interviewee, that should be analyzed.

The relatively open, flexible, and interactive approach to interview structure is generally intended to generate interviewees' accounts of their own perspectives, perceptions, experiences, understandings, interpretations, and interactions. A more standardized and structured approach might overly impose the researcher's own framework of meaning and understanding onto the consequent data. It might also risk overlooking events and experiences that are important from the interviewees' point of view, that are relevant to the research but have not been anticipated, or that are particular to interviewees' own biographies or ways of perceiving. However, some form of aide memoire or interview guide is usually used by the interviewer to ensure that the interview addresses themes identified in advance as relevant to the research.

Semistructured interviewing sometimes implies a particular approach to research ETHICS, whereby the power relationship between interviewer and interviewee is equalized as much as possible, and where the interviewee gets plenty of opportunity to tell his or her story in his or her own way. Although this might make semistructured interviewing appear to be more ethical than standardized and structured methods, it is also recognized that the data generated can be very personal and sensitive, especially where they have emerged in a relationship of trust and close RAPPORT between interviewer and interviewee. Therefore, questions of confidentiality and ethics are not straightforward in this context.

TYPES OF SEMISTRUCTURED INTERVIEW

In practice, there is a range of types of semistructured interviewing. Differences between types tend to center around the extent to which the interviewer is seen to structure and guide the interaction; the nature of the organizing logic for the interview, such as a life story or biography, or a loose topic or set of topics; the extent to which the consequent data are seen to be and are analyzed as interactions or as interviewees' accounts; and the extent to which the interview data speak for themselves or need to be interpreted, by whom and through what mechanisms. Three distinct types of semistructured interview are the following:

1. *The ethnographic interview* is usually part of a broader piece of field research. Ethnographic interviews are often conducted within ongoing relationships in the field, and data of a variety of forms are thus generated both within and outside the interview. They can involve sustained contact between interviewer and interviewee over a period of time, thus extending the possibilities for interactive coproduction of knowledge and for rapport between the parties. In analyzing the consequent data, there is strong emphasis on the interviewees' own interpretations and understandings.

2. *The psychoanalytic interview* is sometimes, although not of necessity, conceived of as part of a therapeutic encounter. The aim is usually to explore not just the interviewees' conscious but also their subconscious understandings. Wendy Hollway and Tony Jefferson (2000) recommend the use of the free association narrative method, which uses a minimum of interviewer-imposed structure to facilitate the researcher's understanding of subconscious intersubjectivity and the psychosocial subject through analysis of interviewees' patterns of free association. The interviewees' own interpretations are thus not taken at face value, and the researcher deploys psychoanalytic theory to analyze the data.

3. *The life or oral history interview* involves generating biographies and life stories. Life histories can be generated in a range of ways, including documentary or visual methods such as analysis of diaries, letters, and photographs. These can become part of the interview, so that, for example, interviewees may be asked to talk about their family photographs. Some approaches use these methods to document lives as they are told, in a fairly noninterpretive way. Others emphasize interpretive and interactive elements in the construction of life

history knowledge. As with ethnographic interviews, life history interviews are sometimes conducted within ongoing relationships over a period of time.

EVALUATION OF SEMISTRUCTURED INTERVIEWING

Semistructured interviewing has been demonstrated to be a valuable method for gaining interpretive data. Criticisms that it produces data that cannot permit comparisons between interviews because they are not standardized are misplaced, because it uses a logic where comparison is based on the fullness of understanding of each case, rather than standardization of the data across cases. However, semistructured interviewing alone can produce only partial interpretive understandings and can be usefully supplemented by other methods, such as those that can extend the situational dimensions of knowledge, including PARTICIPANT OBSERVATION and VISUAL METHODS.

SENSITIVE TOPICS, RESEARCHING

Researchers, not uncommonly, must study topics that are sensitive in some way. There is no definitive list of sensitive topics. Often, sensitivity seems to emerge out of the relationship between the topic under consideration and the social context within which that topic is studied. Seemingly difficult topics can be studied without problems, whereas apparently innocuous topics prove to be highly sensitive. Thus, groups that might seem at first glance to be strange, bizarre, or even frightening sometimes feel misunderstood by the wider society, and regard with equanimity the presence of a researcher whom they feel might convey their worldview to a wider audience. On the other hand,

some apparently normal settings can conceal patterns of deviance participants wish to shield from scrutiny. In these situations, ACCESS and FIELD RELATIONS can become unexpectedly problematic.

Sensitive topics often involve a level of threat or risk to those studied that renders problematic the collection, holding, and/or dissemination of research data. Often, such threats arise from a researcher's interest in particular areas of social life. Research may be sensitive where it touches on aspects of life such as sexual activity, bereavement, or intensely held personal beliefs that are private, stressful, or sacred. The possibility in the eyes of those studied that research might reveal information about research participants that is stigmatizing or incriminating in some way is frequently a source of sensitivity. Research is often sensitive, too, where it impinges on the vested interests of powerful people or institutions, or the exercise of coercion or domination. Research can also pose threats to the researcher. Researchers who study deviant groups sometimes come to share the social stigma attached to those being studied. Friends, colleagues, and university administrators sometimes assume, for example, that researchers investigating aspects of sexual behavior share the predilections of those they study. Physical danger can arise in situations of violent social conflict or when researching groups within which violence is common.

Because they often involve contingencies that are less common in other kinds of study, sensitive topics pose difficult methodological and technical problems. Access to field settings is frequently problematic. Those who control entry to a setting will often decline to provide assistance to the researcher, or surround access with conditions or stipulations. In sensitive contexts, the relationship between the researcher and the researched can become hedged about with mistrust, concealment, and dissimulation in ways that affect the reliability and validity of data. In these situations, acceptance of the researcher is often dependent on the lengthy inculcation of trustful relations with research participants. It is possible to find technical or procedural solutions to the problems caused by the threatening character of the research process, such as collecting data under strongly anonymous conditions. Despite the serious ethical problems involved, some researchers have adopted robust investigative tactics, including covert methods or forceful interviewing strategies, to overcome the tendency of powerful groups to conceal their activities from outside scrutiny.

Sensitive topics raise sometimes difficult issues related to the ethics, politics, and legal aspects of research. Those researching sensitive topics may need to be more acutely aware of their ethical responsibilities to research participants than would be the case with the study of a more innocuous topic. Special care might need to be taken, for example, with anonymization and data protection. Increasingly, research participants have enhanced legal rights vis-à-vis researchers. A number of countries now have regulatory systems that mandate prior ethical review of social research. Sometimes, though, regulatory frameworks hinder research on sensitive topics in ways that arguably run counter to the spirit in which they were framed. Studies deemed too sensitive have sometimes run into difficulty with regulators. Researchers now often enter collaborative research relationships that allow powerless or marginalized groups to voice their concerns and aspirations. PARTICIPATORY or ACTION RESEARCH methods allow for the development of egalitarian and reciprocal relationships between researchers and research participants. Such relationships, however, are not immune to tensions between researcher and researched, or pressures toward co-option.

Sensitive topics tax the ingenuity of researchers and can make substantial personal demands on them. Skill, tenacity, and imagination are all required to cope successfully with the problems and issues that sensitive topics raise. Although these have sometimes encouraged researchers to innovate in areas such as asking sensitive questions on surveys and protecting sensitive data, the relationship between methodological or technical decisions in research and ethical, legal, or political considerations is often complex. Although some researchers deal with the problematic aspects of studying sensitive topics by opting out of such areas altogether, researching sensitive topics remains a challenging and necessary activity for social research.

SENSITIZING CONCEPT

The American sociologist Herbert Blumer, founder of SYMBOLIC INTERACTIONISM, contrasted sensitizing concepts with the definitive concepts insisted on by many QUANTITATIVE social researchers. Sensitizing concepts do not involve using “fixed and specific procedures” to identify a set of phenomena, but instead give “a general sense of reference and guidance in approaching empirical instances.” So, whereas definitive concepts “provide prescriptions of what to see, sensitizing concepts merely suggest directions along which to look” (Blumer, 1969, p.148).

Blumer recognized that vagueness of theoretical concepts can be a problem. However, he denied that the solution was developing definitive concepts, as suggested by the POSITIVIST philosophy of science that had become influential within American sociology in the 1930s, 1940s, and 1950s (see OPERATIONISM). His championing of sensitizing concepts reflected the PRAGMATIST philosophy from which his own thinking about methodology grew. Pragmatists, notably Dewey, argued that concepts are tools for use and should be judged according to their instrumental value in enabling people to understand, and to act on, the world. Also crucial to Blumer’s argument is the idea that concepts have to be developed and refined over the course of research if they are to capture the nature of the phenomena to which they relate. He argued that beginning research by stating precise definitions of concepts, as advocated by many positivists, amounts to a spurious scientificity and is likely to obstruct the task of gaining genuine knowledge about the social world.

At the same time, there are suggestions within Blumer’s work of the more radical view that vagueness, in some sense, may be an inevitable feature of social scientific concepts. One reason for this is the difficulty of capturing the diverse, processual, and contingent nature of social phenomena. Blumer argues that this seems to imply inevitable reliance on tacit cultural knowledge, on *VERSTEHEN*. Thus, he writes that only physical objects can be “translated into a space-time framework or brought inside of what George Mead has called the touch-sight field,” whereas the observation of social phenomena requires “a judgement based on sensing the social relations of the situation in which the behavior occurs and on applying some social norm present in the experience of the observer” (Blumer, 1969, p. 178).

Blumer recognizes that most of the key concepts of sociology fulfill an important sensitizing role. However, he insists that they need to be clarified, as far as this is possible, through researchers enriching their firsthand experience of relevant areas in the social world. This is to be done, above all, by what he calls NATURALISTIC RESEARCH—qualitative or ethnographic inquiry—in which empirical instances are subjected to “careful flexible scrutiny” in their natural context, “with an eye to disengaging the generic nature” of the concept (Blumer, 1969, p. 44).

SENTENCE COMPLETION TEST

A sentence completion test entails filling in one or more missing words in a sentence. A simple example is the following:

She poured him a cup of tea and offered a slice of ____.

The ability to choose semantically appropriate completions is taken to indicate degree of linguistic ability. Alternative versions of the test provide two missing words in order to test understanding of causal or logical relationships, or a full paragraph with multiple missing words.

Sentence completion, or “cloze,” tests are widely used in educational testing (e.g., as part of the American SAT and Graduate Record Exams, and of the Test of English as a Foreign Language). In testing, students are given a range of possible word completions. All are syntactically sound, but only one is semantically appropriate. The validity of completion as a measure of linguistic ability depends on the assumption that understanding the meaning of one term in a natural language requires a supporting structure of many other semantically related terms. Consequently, subjects cannot train to the test because reliable completion performance depends on the degree to which the whole structure is already in place.

In psychological research, subjects are seldom offered multiple completions, but rather allowed to complete the sentence as they think appropriate. The DEPENDENT VARIABLE of interest is then their choice of word, or the time taken to complete the sentence.

Psychological applications divide into two types, depending on whether completions are used as an indirect measure of a nonlinguistic psychological state (e.g., an aspect of personality) or as a tool for investigating language processing itself (e.g., in testing theories of sentence comprehension). In nonlinguistic work, completions provide information about a subject's psychological state only when compared to previously collected completion norms that have been validated for measuring that state.

In psycholinguistics, sentence completion is used in conjunction with free association and priming tasks to quantify otherwise inaccessible and unconscious linguistic expectations (Garman, 1990). In an association task, the subject is given a single word cue and must generate all the words that come to mind. The probability that each word in a language will appear among the first several words after a cue can be estimated from a large body of text. Subjects tend to generate words whose conditional probability given the cue is high. Priming refers to the reduction in time taken to recognize a word caused by brief, prior presentation of a semantically related word, compared to a semantically unrelated one. Priming effects are well predicted by the level of substitutability between the word that is recognized and the prime word. Substitutability is a measure of how easily one word can be replaced with another in context without making the resulting sentences semantically incongruous, and it can be quantified by measuring distributional similarity, the extent to which words share verbal context (Redington & Chater, 1997). Substitutability accounts of meaning are inherently relational and formalize the testing assumption that understanding meaning presupposes substantial surrounding linguistic structure (Cruse, 1986).

Physically, unrelated words in the priming task and incongruous substitutions into sentential contexts trigger large N400 components in brain event-related potentials, lengthened gaze duration, and increased reaction times.

Because the association task is a compressed form of sentence completion, and priming results are predicted by a substitutability measure closely related to that tapped by sentence completion, it is likely that

sentence completion also depends fundamentally on statistical measures of verbal context. On this view, second language applications of the sentence completion task measure how well subjects have internalized the substitutability intuitions that are generated by the underlying statistical properties of the second language and are a necessary by-product of learning to speak it.

SEQUENTIAL ANALYSIS

In the context of social science research, sequential analysis refers to ways of organizing and analyzing behavioral data in an attempt to reveal sequential patterns or regularities in the observed behavior. Thus, unlike LOG-LINEAR or MULTIPLE REGRESSION ANALYSIS, for example, sequential analysis is not a particular statistical technique as such but a particular application of existing statistical techniques.

Data for sequential analysis are usually derived from SYSTEMATIC OBSERVATION (Bakeman & Gottman, 1997), are categorical in nature, and can be quite voluminous. Many of the statistical techniques used are those appropriate for CATEGORICAL DATA ANALYSIS generally, such as chi-square or log-linear analysis, although often a productive strategy is to derive from the data indexes of sequential patterning, which can then be analyzed with any appropriate statistical procedure (Bakeman & Quera, 1995). Thus, a sequential analysis can provide basic descriptive information about sequences of observed behavior. At the same time, it can reduce such data to a few theoretically targeted indexes of sequential process that then can be subjected to any appropriate analytic technique.

HISTORICAL DEVELOPMENT

The development of sequential analysis was spurred in the 1960s by the influence of human and

animal ETHOLOGY and was led largely by researchers interested in animal behavior and human development. Consistent with ethological approaches generally, sequential analysis was viewed as an inductive enterprise: Observers would construct an ethogram (a list of behaviors an animal might perform) and then record the order in which behaviors occurred. Such data consisted of *event sequences*: If the ethogram (or coding scheme) consisted of five codes (e.g., A, B, C, D, E), a data sequence might be A B C B C D E C E C D A, and so on. The notion was, with sufficient data and the right analysis, patterns would emerge.

Thus, researchers formed cross-classified tables: Rows represented the given or current code (Lag 0), columns represented the target or next code (Lag 1), successive pairs of codes in the sequence were tallied (first c_1c_2 , then c_2c_3 , c_3c_4 , etc., where c_i represents the code in the i th position), and cells whose observed frequency exceeded their expected frequency were noted. The extent to which observed frequency exceeds expected frequency can be gauged with an adjusted z score, a common CONTINGENCY TABLE statistic. When codes are many and no targeted hypothesis limits the codes examined, this approach can become unwieldy. For example, in an influential paper from the pre-computer revolution mid-1960s, Stuart A. Altman described covering the floor with patched-together sheets of paper describing matrices with hundreds of rows and columns, down on his hands and knees, looking for patterns.

LAGGED EVENT SEQUENCES

Given event sequences, typically Lag 1 tables prove most useful, but Lag 2, Lag 3, and so on (columns represent second behavior, third behavior, etc., after current one), can also be considered in an arrangement that Gene P. Sackett (1979) termed lag-sequential analysis. For example, if B occurred significantly more often after A at Lag 1, and C occurred significantly more often after A at Lag 2, this would suggest that A B C was a common sequence, especially if C occurred significantly more often after B at Lag 1. Such analyses are most useful when the duration of events does not vary much and when order and not timing is of paramount concern.

TIMED SEQUENCES: AN EXAMPLE

The previous example assumed that events were coded in sequence but that their onsets or offsets were

Table 1 Toddler's Onsets of Rhythmic Vocalizations Cross-Classified by Whether or Not They Occurred Within 5 Seconds of Mother's Onsets

<i>Within 5 s of Mother's Onset</i>	<i>Toddler Onset</i>		<i>Totals</i>
	<i>Yes</i>	<i>No</i>	
Yes	11	189	200
No	29	97	1,000
Totals	40	1,160	1,200

NOTE: This mother-toddler dyad was observed for 1,200 seconds or 20 minutes; the tallying unit is the second.

not timed. When timing information is available—and the current digital revolution makes timing information ever easier to record—sequences can be represented and analyzed in ways that provide analytic opportunities not available with event sequences. Assume that times are recorded to the nearest second. Then, *timed sequences* can consist of any number of mutually exclusive or co-occurring behaviors, and the time unit, not the event, can be used as the tallying unit when constructing contingency tables. This can be very useful. Often, researchers want to know whether one behavior occurred within a specified time relative to another and are not particularly concerned with its lag position, that is, with whether other behaviors intervened.

For example, Deckner, Adamson, and Bakeman (2003) wanted to know whether mothers and their toddlers matched each other's rhythmic vocalizations and so coded onset and offset times for mothers' and toddlers' rhythmic vocalizations. Table 1 shows results for one dyad.

For the rows, seconds were classified as within a 5-second window defined by the second the mother began a rhythmic vocalization or not; for the columns, seconds were classified as a second the toddler began a rhythmic vocalization or not. A useful way to summarize this 2×2 table is to note that the odds the toddler began a rhythmic vocalization within 5 seconds of his or her mother beginning one were 0.0582 to 1 or 1 to 17.2, whereas the corresponding odds otherwise were 0.0299 to 1 or 1 to 33.5. Thus, the ODDS RATIO—a statistic probably used more in epidemiology than in other social science fields—is 1.95.

The ODDS RATIO is useful on two counts: First, it is useful descriptively to say how much greater the odds are that a behavior will begin within a specified time window than not. Second, the natural logarithm

of the odds ratio, which varies from minus to plus infinity with zero indicating no effect, is an excellent score for standard statistical analyses (the odds ratio itself, which varies from zero to plus infinity with 1 representing no effect, is not). Thus, Deckner et al. could report that 24-month-old females were more likely to match their mother's rhythmic vocalization than 24-month-old males or either male or female 18-month-old toddlers.

In sum, Deckner et al.'s study provides an excellent example of how sequential analysis can proceed with timed sequences. Onset and offset times for events are recoded; a computer program (Bakeman & Quera, 1995) then tallies seconds and computes indexes of sequential process (here, an odds ratio) for individual cases; and finally, a standard statistical technique (here, mixed model ANALYSIS OF VARIANCE) is applied to the sequential scores (here, the natural logarithm of the odds ratio).

SEQUENTIAL SAMPLING

Sequential SAMPLING involves drawing multiple SAMPLES and administering them one after another until, cumulatively, they meet the objectives of the survey. Frequently, it is difficult or impossible to know in advance what the response rate or cost per interview will be for a particular survey, especially for special POPULATIONS or when response patterns are changing. In these cases, it is difficult to accurately project the size of the sample that must be drawn in order to meet research objectives such as obtaining the desired number of completed responses or staying within the budget for data collection. Sequential sampling

relies on the principle that PROBABILITY SAMPLES drawn from the same study population can be combined and estimates calculated as if they were initially drawn as a single sample. Sequential sampling allows researchers to control more precisely the number of completed responses obtained by a survey without unduly compromising the criteria of probability selection or absence of NONRESPONSE (Kish, 1965).

Sequential sampling is often implemented by drawing three samples: an initial sample of one-half the size that could be optimistically expected to meet the study objectives; an additional sample of the same size as the first drawn from the same population; and a final, supplemental sample that is drawn from the same study population. The sample that is optimistically expected to meet the study objectives can be calculated using somewhat but not too ambitious response rates. This is generally done by dividing the response rate into the number of completed responses desired by the survey and using this as the optimistic sample size for data collection ($n_o = n/r$, where n_o is the optimistic size of the sample needed for data collection, n is the number of completed responses desired, and r is an optimistic estimate of the response rate). In practice, the first sample ($n_o/2$) is fully administered using all of the callback procedures specified in the survey design. When the data collection for the first sample is nearly completed, the second sample is placed in the field and data collection proceeds as planned. Researchers calculate estimates of nonresponse and cost per interview from the first sample. Using these estimates, the size of the third sample is calculated, the third sample is drawn from the same study population, and it is placed in the field for data collection according to the survey design. Sequential sampling allows researchers to hedge their bets against uncertain outcomes.

Although it provides obvious benefits, sequential sampling can increase costs of field operations and make survey administration more difficult. A common problem with sequential sampling has been the interruption of field operations while the results from the first sample were tabulated. The use of the second sample in the steps above minimizes the disruption to field operations. In addition, it is now common for interviewers to enter data directly into automated files, reducing the time needed for the calculations that are required to establish the size of the final sample.

Although the three-sample, sequential sample, described above, is generally adequate for obtaining CROSS-SECTIONAL survey data, the technique has

been expanded in two ways. First, telephone survey administrators often obtain multiple samples or replicates from commercial sampling firms that are administered as sequential samples, usually with several replicates being administered at the beginning of the survey and additional samples being activated for data collection as response rates are estimated from the first batch of samples. Because commercial sampling firms constantly update their files of useable telephone numbers and charge set-up fees for each separate sample, many telephone survey units routinely obtain excess samples in several replicates to maximize control over the uncertainties of data collection while controlling their costs.

Second, sequential sampling techniques are employed in tracking polls or rolling sample surveys that allow both cross-sectional and TIME-SERIES estimates from the study population. Tracking polls are used primarily in political campaigns by candidates, media outlets, and scholars (John, 1989; Moore, 1999; Rhee, 1996). Tracking polls allow estimates of the current level of support for a candidate and change in the support over time (Green, Gerber, & De Boef, 1999). Usually, a sample replicate is opened for data collection every day, and candidate support is estimated as 3- or 5-day MOVING AVERAGES. Rolling sample surveys use similar techniques to investigate a broader range of social science research questions, such as the dynamics of opinion change (Henry & Gordon, 2001).

SERIAL CORRELATION

Serial correlation exists when successive values of a TIME-SERIES process exhibit nonzero COVARIANCES.

The term *serial correlation* is often used synonymously with autocorrelation, which refers to the more general case of correlation with self and may be either over time, as when the president’s approval rating today is correlated with his approval rating yesterday (serial correlation), or across space, as when gang membership is correlated with physical distance of residence from an inner city (SPATIAL correlation). Spatial correlation is less pervasive than serial correlation and is seldom discussed at any length in textbook treatments of autocorrelation. Serial correlation is a common feature of time-series processes and has implications for dynamic MODEL SPECIFICATION. The presence of serial (or spatial) correlation in the errors of a REGRESSION model violates the GAUSS-MARKOV regression ASSUMPTIONS and invalidates inference from OLS estimates.

A time-series process is serially correlated if its value at time t is a LINEAR function of some number, p , of its own past values:

$$y_t = a + b_1 y_{t-1} + b_2 y_{t-2} + \cdots + b_p y_{t-p} + \mu_t.$$

If y_t is correlated only with y_{t-1} , then we say that we have first-order serial or autocorrelation, often denoted ρ_1 . If y_t is correlated with y_{t-1} and also with y_{t-2} , we have second-order autocorrelation, denoted ρ_2 , and so on. The autocorrelations themselves, the ρ , give the strength of CORRELATION. Serial correlation does not depend on the time period itself, only on the interval between the time periods—the length of the LAG—for which the correlation is being assessed. The correlation between y_t and y_t is perfect or 1 ($\rho_0 = 1$). The estimated serial correlations give us a sense of the nature and extent of the time dependence inherent in the y_t process. For first-order serial correlation, by far the most common case, the correlations at successive lags will decay at a rate determined by ρ_1 , with large correlations indicating stronger time dependence and slower decay.

If a series is covariance stationary (the mean, variance, and lagged covariances are constant over time), we can define the autocorrelations between y_t and y_{t-p} as the covariance between y_t and y_{t-p} divided by the autocovariance (variance) of y_t . Furthermore, for a stationary series, the correlations range from -1.0 to 1.0 , with larger magnitudes characteristic of stronger over-time dependence.

EXAMPLES

Typically, social processes will exhibit positive rather than negative serial correlation: Successive

observations will tend to move in the same direction—either up or down—over time. Consider some examples.

- Government or agency budgets are based on the previous budget(s) and are not created anew each year, so that changes in the process are incremental. Correlations in adjacent periods will be strong and positive.
- The aggregate partisan balance (percent of Democrats, for example) tends to move only sluggishly, presumably because features of the political system keep the balance of partisanship from varying wildly over time. This produces strong positive serial correlation in the partisan balance.
- The percent of women working in professional or managerial positions has tended to increase slowly over time as mean levels of education of women increased, producing strong positive correlations between adjacent values.

In contrast, negative serial correlation occurs when the current value of a process is related to its past in such a way that the signs on the b above oscillate. A process that adjusts over time for some sort of error in the past realization would create negative correlation, where in one time period, the process goes up, and then in the next, it goes down.

IMPLICATIONS

Serial correlation has two types of implications for MODELING. First, the analyst must be sensitive to time-series dynamics when selecting a model specification. Serial correlation in the processes we care about should be directly modeled by including lags of the dependent, and possibly independent, variables in regression models of the process. Second, analysts must also be aware that the error process in a dynamic regression may itself be serially correlated; the errors in one time period may be related to past errors in a systematic way, even after care has been taken to model dynamics directly. Most typically, the PREDICTION error is systematically too high or too low, producing positive serial correlation in the model errors. Serial correlation in the errors of a regression model violates the regression assumption that the errors are uncorrelated and invalidates inference by BIASING the estimated STANDARD ERRORS. The direction of the bias varies with the sign of the correlation, with positive correlations

deflating the standard errors and negative correlations inflating them. Given that social science processes tend to exhibit positive correlation, the variance typically will be underestimated (we inflate our estimate of the precision of our estimates), making it likely that the analyst may reject a true null hypothesis. In addition, R^2 is overestimated in this case. More generally, given serially correlated errors, t - and f -tests are no longer valid and will be misleading (Gujarati, 2002).

Given the high cost associated with drawing INFERENCES from models with serially correlated errors, good practice when estimating REGRESSION models involving time-series data includes postestimation diagnostic tests for serial correlation in the error process. The most common of these is the DURBIN-WATSON test for first-order autocorrelation.

Evidence for serial correlation in the errors may occur for several reasons. First, the evidence may be due to dynamic MISSPECIFICATION. This may occur for several reasons, such as the following:

- Excluding variables whose behavior is time dependent will produce serial correlation in the regression error; the error term will include the omitted time-dependent variable. If we omit September 11th from a model of President Bush's approval ratings, for example, we will underestimate his approval systematically after that time period. In this case, there would be strong positive autocorrelation in the errors.
- Incorrect FUNCTIONAL form can produce serial correlation. If we estimate a regression between X and Y , but Y is linearly related to the square of X , we will systematically overestimate a series of consecutive Y s and then consistently underestimate a series.
- Omitting a lagged term when the dependent variable is inertial will produce serial correlation.

Dynamic misspecification is best handled with changes in the specification of the dynamics.

Alternatively, the underlying errors themselves may be serially correlated. This may be due to problems with the data, for example. Data manipulation—INTERPOLATING MISSING values, SMOOTHING time series to deal with RANDOM fluctuations in the data (averaging consecutive observations), or aggregating over time—may lead to systematic patterns in the disturbances. In these cases, remedial measures such

as (feasible) GENERALIZED LEAST SQUARES (GLS) are required for valid inferences.

ADDITIONAL ISSUES

The discussion above focuses on serial correlation in the context of stationary time-series processes. Stationary processes represent an important class of time-series processes that are stable, having a constant mean, variance, and covariance for all time periods. Serial correlation patterns for stationary time series exhibit rapid decay—the recent values of the time series are related more strongly to its value today than are time points in the past—and the rate of decay in the strength of the correlations is predictable and quick. But serial correlation may take many forms. If a series is not stationary, serial correlations at successive lags may be equal to or even greater than 1. In the former case, the effects of the past do not decay, but cumulate over time. Serially correlated processes that do not exhibit decay in their correlations are called unit root or RANDOM WALK processes. Patterns of serial correlation that reveal stronger correlations at longer lags are called explosive processes. Both of these types of processes are examples of integrated processes. Alternatively, serial correlations may decay over time but decay so slowly that effects persist even at long lags. This class of processes is called fractionally integrated. Traditional PROBABILITY theory does not apply to non-stationary processes of any type, so that these series must be TRANSFORMED in some way to make them stationary before hypothesis tests can be conducted and inferences about social processes can be made.

variance (or, alternatively, as the squared PEARSON'S CORRELATION COEFFICIENT between the sample values and their normalized expected standard normal-order statistics). Formally,

$$W = \frac{(\sum_{i=1}^N a_i X_i)^2}{\sum_{i=1}^N (X_i - \bar{X})^2} \quad (1)$$

where the X_i are the *ordered* values of the sample data $\mathbf{X}$ (from lowest to highest) and a_i are the normalized standard normal-order statistics $\mathbf{m}' = (m_1 \dots m_N)$ with variance-covariance matrix $\mathbf{V}$, such that $\mathbf{a}' = (a_1 \dots a_N) = \mathbf{m}'\mathbf{V}^{-1}[(\mathbf{m}'\mathbf{V}^{-1})(\mathbf{V}^{-1}\mathbf{m})]^{-1/2}$ is anti-symmetric and, by construction, $\mathbf{a}'\mathbf{a} = 1$. Under the null hypothesis of normality, W converges asymptotically to the distribution outlined in Shapiro and Wilk (1965). Low values of the test statistic support rejection of the NULL HYPOTHESIS that the data are normally distributed.

The original Shapiro-Wilk test was designed for sample sizes between 3 and 50; more recent modifications of the test have increased its usability up to N s of 2,000 (see Royston, 1993, for an overview), whereas the Shapiro-Francia W' test is valid for sample sizes up to 5,000. The test is scale and origin invariant, and is very robust to departures from non-normality; for these reasons, it is generally held to be a superior alternative to most other normality tests (e.g., the Bera-Jarque moment test and the Lilliefors modification of the KOLMOGOROV-SMIRNOV TEST).

As an example, consider the data on aggregate IQ scores from 81 countries given in Gill (2002, p. 103). The testing instrument is designed to give a mean response of 100, with a variance of 15; by contrast, the sample data have a mean of 88 and a variance of 12. The Shapiro-Wilk statistic W equals 0.944, whereas the Shapiro-Francia W' equals 0.950; both allow us to reject the null hypothesis of normality at $p < .01$.

—Christopher Zorn

SHAPIRO-WILK TEST

The Shapiro-Wilk test (typically called “ W ”) is a test for the NORMAL DISTRIBUTION of a RANDOM VARIABLE. Intuitively, this is obtained as the ratio of the square of the LINEAR COMBINATION of standard normal-order statistics to the sample

SHOW CARD

A show card is a visual device used in standardized QUANTITATIVE face-to-face survey INTERVIEWING. It is so called because it is traditionally made of cardboard and is used to show the interviewee certain information. Typically, the information on the card consists of a list of possible answers to a question, from which the interviewee will be asked to select one or more, as appropriate. The main reason for using a show card is to overcome the difficulties that many interviewees would have retaining the response options in their head if the interviewer were simply to read them out, without providing any visual aid.

These difficulties in the absence of a show card sometimes lead to “recency effects,” whereby interviewees may tend to choose the last, or one of the later, options (i.e., the ones most recently read out) because the earlier ones are less memorable. Consequently, a show card may be used if there are many response options (say, more than three or four), or if the options are long and/or complex (e.g., phrases to describe a range of possible views on a topic). However, show cards do not overcome all problems associated with predetermined lists of response options. In some circumstances, responses may be subject to “primacy effects,” whereby interviewees tend to choose the first option that seems to apply in order to save the cognitive burden and time associated with reading the whole card in full.

Another use of a show card is to serve as a memory jogger for an OPEN-ENDED QUESTION. For example, a question asking whether the interviewee has performed any kind of voluntary activity in the past 7 days may utilize a show card listing some examples of voluntary activity in order to provide an idea of the kinds of activities in which the researcher is interested. This technique can help to prompt responses that otherwise may be omitted, but it may also lead some interviewees to focus only on listed items. In other words, interviewees may treat the list as exhaustive rather than as examples.

Show cards can also be used to display material that cannot adequately be communicated verbally. For example, an interviewee could be shown a copy of a newspaper advertisement and asked whether he or she recalls seeing it. In practice, such material acts in a way that is not very different from that of the textual memory jogger. It may prompt recognition that

would not have occurred if the interviewer had simply described the advertisement verbally, but on the other hand, it may also trigger false recognition.

The ability to use show cards (and other visual aids) is often considered to be an important advantage of face-to-face survey interviewing over telephone survey interviewing. Show cards are not free of problems, however. Unlike verbally delivered questions, they require a degree of literacy on the part of the interviewee, and this can become a source of RESPONSE BIAS. There is also the risk of primacy effects. It might be noted, however, that these issues also apply to SELF-COMPLETION surveys. The logistical aspects of the use of show cards are also important. Show cards must be produced in a way that allows easy turning from one to the next and must be (and must remain) in the correct order. (Loose-leaf cards are not a good idea.) The cards should be labeled clearly, and the interviewer should be provided with clear instructions on which card is to be used at which point in the interview (e.g., “Now look at card C . . .”).

—Peter Lynn

SIGN TEST

The sign test, in its simplest form, provides a comparison of the probabilities of two types of outcomes. The same procedure can be used to make inferences about the mean of a population of differences.

Suppose a RANDOM SAMPLE of 22 registered voters is asked whether they intend to vote for Candidate A or Candidate B in the upcoming election. Seven voters say they favor Candidate A, 12 prefer Candidate B, and three are undecided. Does this indicate a significant preference for Candidate B over Candidate A? We ignore the three undecided voters, on the basis that they are equally likely to end up voting for either candidate, and consider the remaining $n = 19$ voters with 12 “successes” for Candidate B. The test is based on this number S of successes in the sample. If the candidates are equally preferred, the PROBABILITY of a success for Candidate B from any voter would be 0.5, the same as for Candidate A. The probability of $S = 12$ or more successes for Candidate B is calculated from the BINOMIAL DISTRIBUTION as

$$P(S \geq 12) = \sum_{s=12}^{19} \binom{19}{s} (0.5)^s (0.5)^{19-s} = 0.1796.$$

This value is not particularly small, and we conclude that this sample does not provide sufficient evidence to conclude that B is significantly preferred over A. For larger sample sizes, the test is based on the NORMAL approximation to the binomial distribution (with a continuity correction), calculated from

$$Z = \frac{S - 0.5 - (n/2)}{0.5\sqrt{n}} = 0.92.$$

This normal approximation gives $P = 0.1788$, which is extremely close to the exact value.

The other type of application of the sign test is when we have a random sample of n pairs of observations $(X_1, Y_1), (X_2, Y_2), \dots, (X_n, Y_n)$ drawn from a bivariate distribution. We want to make an inference about the mean differences between the X s and Y s in the population. The first step is to take the differences $D_i = X_i - Y_i$ between the X and Y observation in each pair. Because the difference between the X and Y population means is the same as the mean μ_D of the $D = X - Y$ population of differences, the null hypothesis is $H_0 : \mu_D = 0$.

To carry out the sign test, we take the differences $D_1, D_2, \dots, D_n$ and note the number S of plus signs among these differences. If the alternative is $H_1 : \mu_D > 0$, the test rejects for large values of S , or equivalently, the P VALUE is in the right tail of the binomial distribution with probability of success $p = 0.5$. This application of the sign test is a special case of the BINOMIAL test of the null hypothesis that $p = p_0$ against the alternative that $p > p_0$.

As an example, suppose 10 married couples are randomly selected to determine the relationship between ratings of husbands and wives concerning the taste, convenience, and cost of frozen croissant pizza. The responses were on a scale of 0 (terrible product) to 100 (excellent product). The data are shown in Table 1. Do the husbands like the product better than their wives?

We ignore the one couple who gave the same rating. Of the remaining nine differences, eight husbands liked the product better than their wives. The probability of this occurring under the null hypothesis of equal

preference is $P(S \geq 8) = 0.0195$. With a p value this small, we reject the null hypothesis and conclude that the mean preference rating from husbands is larger than the mean rating from wives.

—Jean D. Gibbons

SIGNIFICANCE LEVEL. See ALPHA, SIGNIFICANCE LEVEL OF A TEST

SIGNIFICANCE TESTING

Significance testing provides objective rules for determining whether a researcher's HYPOTHESES are supported by the data. The need for objectivity arises from the fact that the hypotheses refer to values for POPULATIONS of interest, whereas the data come from SAMPLES of varying reliability in representing the populations. For example, the population of interest may be people of college age, and the sample may be students from a particular class who are available at the time the data are collected. This, of course, would not represent a RANDOM SAMPLE, which would be ideal, but does represent a "handy" sample often used in social science research. (Extrastatistical considerations come into play when deciding the extent to which the data from a "handy" sample generalize beyond that sample. For example, the results of a study on visual perception with a handy sample of college students should be readily generalizable.) To conclude that a particular VARIABLE influences behavior, the researcher must follow the principles of good research design in obtaining and recording the data. No amount of statistical "massaging" of the data can rescue a poorly designed study.

Even when the data come from a well-designed study, just showing that there are differences between the scores for, say, two groups is not enough. The researcher must also demonstrate that differences in behavior between the two groups are RELIABLE; that is, they are greater than differences attributable to chance.

Chance, or, more formally, chance sampling effects, refers to preexisting differences between samples of individuals that have nothing to do with how they are classified or treated in a research study. Chance sampling effects might be substantial in a study of

Table 1 Data on Preferences

Couple	1	2	3	4	5	6	7	8	9	10
Husband	76	83	60	90	100	55	62	69	75	43
Wife	71	81	62	84	65	44	61	67	75	40
Difference	+	+	−	+	+	+	+	+	0	+

human behavior where the subjects' prior history of genetic and environmental influences is beyond the researcher's control. In order to eliminate any systematic bias in the assignment of subjects to conditions based on the uncontrolled factors, researchers typically use RANDOMIZATION to assign subjects to conditions such that all subjects have the same chance of being assigned to any condition. This is a more crucial application of randomness than selecting subjects from a population that may be imprecisely defined.

Even with the use of randomization, however, a measure such as the sample MEAN can vary considerably from sample to sample even if the populations from which the samples are drawn are equivalent. This variation is due to the fact that different individuals fall into different samples, and each individual has unique characteristics. So, of course, the samples will vary one from the other. This will be especially true when sample size is low and a few discrepant scores can skew the results. Later, when we develop a specific example, we will see that sample size plays a crucial role in significance testing. To preview that illustration, the smaller the sample size, the larger the mean difference between groups has to be in order to demonstrate a statistically significant difference.

The formal process by which the researcher determines whether a difference is "statistically significant," that is, whether it represents more than chance variation, is known as HYPOTHESIS TESTING.

HYPOTHESIS TESTING

Most research questions in the social sciences boil down to two competing hypotheses. The competing hypotheses are referred to as the null hypothesis and the alternative hypothesis. The NULL HYPOTHESIS (H_0) is the hypothesis initially assumed to be true. In most cases, H_0 assumes no difference (e.g., the experimental treatment has no effect), whereas the ALTERNATIVE HYPOTHESIS (H_a) typically affirms the existence of differences among experimental conditions. The null hypothesis does not usually correspond to the actual prediction of the experiment. It is more like a "straw man" that the researcher hopes to discredit. However, because the null hypothesis is stated as an equality (e.g., the difference between the population mean scores of the experimental and control groups is zero) and the alternative hypothesis is stated as an inequality (the difference between the means is not equal to zero), only H_0 can be tested directly, and that is why we start with

that hypothesis even though it is not the actual research hypothesis. Examples of null hypotheses include the following statements: a drug has no effect; individuals will make the same decisions whether they are alone or in groups; there is no relation between income and political party affiliation; men and women receive equal pay for the same work. To affirm the existence of an effect or a RELATIONSHIP, the researcher must first reject or nullify H_0 (that is why it is called the "null" hypothesis) by providing data that are inconsistent with the assumption of no effect. Hence, the term *indirect proof* or *indirect support* has been adopted.

In testing these hypotheses, the particular statistical test used (e.g., *T-TEST*, ANALYSIS OF VARIANCE, REGRESSION, CHI-SQUARE TEST) will depend on features used to generate the data being tested. These include whether the study was designed to examine differences between experimental conditions or measure the strength of ASSOCIATIONS between sets of observations, the type of data collected (e.g., numerical data or frequency counts), and the number of factors (variables) in the EXPERIMENTAL DESIGN. The flow chart in Figure 1, reprinted from Levin (1999), illustrates the selection of tests based on these considerations (see also Howell, 2002, and Tabachnick & Fidell, 2001).

Regardless of the particular statistical test that is appropriate for a given set of data, the logic is similar. A measure is taken of the difference between conditions or degree of association that is actually observed in the sample data. This is then compared to the value expected if the null hypothesis were actually true, that is, no difference between conditions or no association between sets of observations, and only chance factors were influencing the data. *The greater the extent to which the observed differences exceed those expected by chance, the less the likelihood that the differences were due to chance and the more likely they were actually due to something else.* In a well-designed experimental study, that "something else" would be the effect of the INDEPENDENT VARIABLE manipulation on the DEPENDENT VARIABLE. In a well-designed OBSERVATIONAL study, the "something else" could be differences between categories of people such as Republicans and Democrats on behaviors such as amount of money donated to candidates for political office.

Modern computational procedures allow us to compute the PROBABILITY (the so-called *P VALUE*) that a given set of data could have been the result of chance

Figure 1 Selection of Tests

SOURCE: Levin, 1999.

factors alone, that is, that the null hypothesis was actually true. The lower this probability is, the less likely it is that the null hypothesis was true. So, we reject H_0 in favor of H_a when p is low and we retain H_0 when p is high. But what constitutes “low” or “high” values of p ? We had said earlier that significance testing provides objective rules for testing hypotheses. Here, some subjectivity is exercised. Clearly, if $p < .01$, we would want to reject H_0 because there is less than 1 chance in 100 that we could have gotten the data we did if the null hypothesis were true. And clearly, if $p > .25$, we would have to retain H_0 because the results could well have been due to chance. What about values in between?

These cases involve consideration of the types of errors that can be made in testing statistical hypotheses. Errors occur when H_0 is true, but you reject it in favor of H_a , or when H_0 is false, but you retain it. By convention, these two types of errors are called TYPE I ERRORS and TYPE II ERRORS, respectively. The probability of a Type I error (called ALPHA and denoted α) and the probability of a Type II error (called BETA and denoted β) are inversely related. If a strict criterion is set for rejecting H_0 , then H_0 will seldom be rejected when it is true, but H_0 is apt to be retained when it is false, resulting in a low level of alpha and a relatively high level of beta.

The opposite occurs with a lax criterion for rejecting H_0 . This criterion is called the LEVEL OF SIGNIFICANCE, which can be set ahead of time as low (e.g., $\alpha = .01$) to reduce the probability of a Type I error or high (e.g., $\alpha = .10$) to reduce the probability of a Type II error. This decision should be based on the judged relative severity of Type I and II errors. For example, in medical research, a Type I error could mean that an ineffective drug or treatment was said to have an effect, and a Type II error could mean that a helpful drug or treatment was said to have no effect. Thus, a medical researcher testing the effectiveness of a new drug might want to set $\alpha = .01$ to avoid premature marketing of an unproven drug. In practice, an intermediate level of $\alpha = .05$ is often used.

AN EXAMPLE

The t -test is most often used to compare the means of two groups or conditions. The null hypothesis is that the population mean scores are equal for the two conditions. In other words, no difference would be found if we could compare the entire population of scores for the two conditions, $H_0 : \mu_1 - \mu_2 = 0$, where μ_1 and μ_2 represent the population mean values for the two conditions. But the data, of course,

come from samples, not entire populations. In a study of aggressive behavior in children, for example, one group or condition could be a sample of heavy viewers of violence on TV, and the other could be a sample of light viewers. The alternative hypothesis is that there is a difference, $H_a : \mu_1 - \mu_2 \neq 0$. (If the direction of difference were predicted ahead of time, a ONE-TAILED version of H_a would be specified, such as $\mu_1 - \mu_2 > 0$.)

The test assumes that the distribution of scores in each condition is NORMAL and that the two distributions have equal variance. There is considerable evidence, however, that the t -test is relatively unaffected by moderate deviations from these assumptions when sample sizes are equal. The following values are computed for the two samples of scores obtained in the study: the means, $\bar{X}_1$ and $\bar{X}_2$; the STANDARD DEVIATIONS, s_1 and s_2 ; and the sample sizes, n_1 and n_2 . (Note that Greek letters are often used to denote population values, and Latin letters are used to denote sample values. This is done to clearly distinguish population from sample. Hypotheses are stated for the populations of interest; they are tested with data from samples.) The value of t is then computed using the following formula for the case of equal sample size, $n_1 - n_2 = n$:

$$t = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{(s_1^2 + s_2^2)/n}}.$$

Note that the numerator is a measure of how much the sample means actually differed, whereas the denominator contains measures of variability that represent the influence of chance. The larger the ratio, the more likely the results represent more than chance variations.

The resulting value of t is then compared with the CRITICAL VALUE found in a table of the t statistic using the selected level of α and the appropriate DEGREES OF FREEDOM, $df = (n_1 - 1) + (n_2 - 1) = 2(n - 1)$ in our case. The critical value defines that portion of the tail or tails of the distribution of the t statistic that represents an area equal to α . This area is called the critical region. If the absolute value of t calculated from the data is larger than the value in the table, then the decision is to reject H_0 in favor of H_a . If the calculated absolute value of t is less than the value in the table, then H_0 must be retained as a viable option. The rationale in the case of retaining H_0 is that the observed difference is not sufficient in magnitude to conclude that the two conditions are different. The rationale in the case of

rejecting H_0 is that the observed difference between the means of the two samples is too great to be attributable to chance, so the researcher concludes that scores for the two groups are truly different. This is often referred to as a STATISTICALLY SIGNIFICANT difference.

To provide a numerical illustration, suppose that the mean rating by parents and teachers of each child's aggressive behavior on a scale of 1 to 7 was 5.0 for the heavy viewer group and 3.6 for the light viewer group. Further suppose that the standard deviation of the scores for each group was 2.0. To underscore the importance of sample size, let's first consider that these data came from a sample of 10 children in each group and then consider samples of size 25. In the case of samples of size 10, the value of t turns out to be 1.57, which, with degrees of freedom of 18, is not significant (does not exceed the critical value) for the traditional .05 level of significance. In the case of samples of size 25, the value of t turns out to be 2.47, which, with degrees of freedom of 48, is significant. Thus, only in the latter case would the researcher conclude that the result was statistically significant and that the null hypothesis of no effect of type of TV exposure can be rejected in favor of the alternative hypothesis that the group of children who watched much violence on TV committed more aggressive acts than the group who watched little violence on TV.

SUMMARY

SIGNIFICANCE TESTING is designed to provide a decision rule based on an estimate of the probability or likelihood that a given set of research results was due merely to chance factors varying randomly between different conditions. When the likelihood of obtaining a set of results by chance is estimated to be less than a predetermined level of significance, the most reasonable conclusion is that the results are due to more than just chance and the decision is to reject the hypothesis of no effect. If the research has been designed and conducted appropriately, the researcher may then conclude that the factor of interest—the independent variable being manipulated, for instance—had a likely effect on behavior.

SIMPLE ADDITIVE INDEX. See MULTI-ITEM MEASURES

SIMPLE CORRELATION (REGRESSION)

Simple CORRELATION is a measure used to determine the strength and the direction of the relationship between two variables, X and Y . A simple correlation coefficient can range from -1 to 1 . However, maximum (or minimum) values of some simple correlations cannot reach unity (i.e., 1 or -1). Given there are two sets of observations deviating from the correspondent means, $x_1, x_2, \dots, x_n$ and $y_1, y_2, \dots, y_n$, a generalized simple correlation (r_{xy}) can be defined as

$$\frac{\sum_{i=1}^n x_i y_i}{\sqrt{\sum_{i=1}^n x_i^2 \sum_{i=1}^n y_i^2}}$$

or

$$\frac{\text{cov}(X, Y)}{s_X s_Y}.$$

s_X^2 and s_Y^2 are VARIANCES of the variables X and Y , and $\text{cov}(X, Y)$ is the COVARIANCE between the variables X and Y . Examples of this generalized simple correlation include Kendall's TAU coefficient, SPEARMAN CORRELATION COEFFICIENT, and PEARSON CORRELATION COEFFICIENT.

A simple correlation between variables X and Y does not imply that either variable is an INDEPENDENT VARIABLE or a DEPENDENT VARIABLE. An observed relationship between job satisfaction and job performance reveals little as to whether satisfied employees are motivated to perform well, or those who perform well are proud of themselves, which, in turn, makes them feel more satisfied with their jobs. Furthermore, a simple correlation may or may not reflect the real association between two variables because the relationship can be influenced by one or more third

variables. For instance, the observed relationship between school grade and intelligence for a group of elementary students could be influenced by students' socioeconomic status.

Assuming there is a linear relationship between the variables X and Y , we can use variable X to predict variable Y , or vice versa, with two REGRESSION equations, $Y = a_1 + b_{y.x}X + e_1$, and $X = a_2 + b_{x.y}Y + e_2$. Both $b_{y.x}$ and $b_{x.y}$ are the REGRESSION COEFFICIENTS, a_1 and a_2 are INTERCEPTS, and e_1 and e_2 are the RESIDUALS in variables X and Y that cannot be predicted by variable Y or variable X , respectively. Because $b_{y.x} = r_{xy} \frac{s_y}{s_x}$ and $b_{x.y} = r_{xy} \frac{s_x}{s_y}$, $r_{xy} = \sqrt{b_{y.x} b_{x.y}}$. Conceptually, a simple correlation in this case is a geometric mean of two regression coefficients, $b_{y.x}$ and $b_{x.y}$. Furthermore, r_{xy}^2 represents the proportion of variance accounted for by using either variable Y to predict variable X , or variable X to predict variable Y .

There are numerous simple correlations used to assess relationships with different characteristics. Some correlations are appropriate for assessing a MONOTONIC relationship (e.g., Spearman correlation coefficient), a LINEAR RELATIONSHIP (e.g., Pearson's correlation coefficient), or an ASYMMETRIC RELATIONSHIP (e.g., Somer's d). A positive or a negative monotonic relationship indicates that both variables are moving in the same direction or in opposite directions, respectively. A linear relationship, a special case of a monotonic relationship, implies that X can fairly predict variable Y (or vice versa) based on some linear function rules (e.g., $Y = a + bX$). An asymmetric relationship can occur when variable Y perfectly predicts variable X , but not vice versa.

The simple correlation can be generalized to more than two variables, such as the MULTIPLE CORRELATION COEFFICIENT or the CANONICAL CORRELATION. Whereas the former assesses the relationship between a variable (i.e., criterion) and a set of other variables (i.e., predictors), the latter measures the relationship between two sets of variables. Furthermore, simple correlation can be used for variables measured at any of the LEVELS OF MEASUREMENT. For example, we can assess the relationship between age (RATIO scale) and gender (NOMINAL scale), between Fahrenheit temperature (INTERVAL scale) and electricity consumption (ratio scale), or between letter grade (ORDINAL scale) and religion (NOMINAL scale).

SIMPLE OBSERVATION

Simple observation techniques generate research DATA that are direct and immediate, that is, not generated or colored by interpretation, artificial EXPERIMENTAL conditions, memory, or other factors. Observational data may bear upon some perspective held by the observer, or they may be used to help develop a theory at a later time. They are often used in research areas that are not yet well developed, where careful observation can generate HYPOTHESES for future research.

Several pitfalls affect data gathering and interpretation in observational research, as described, for example, in Rosenthal (1976) and texts on social science methods (e.g., Lee, 2000). One is the question of hardware, that is, whether recording of the observed behavior is to be carried out, and whether it can be done without BIAS, without the consent or awareness of research participants, or without prohibitive ETHICAL difficulties.

Another pitfall is that observational data, if not standardized or permanently recorded for research use (and thus amenable to repeated scrutiny and VERIFICATION), may generate unreliable data when provided, for example, by multiple eyewitnesses to an event, or untrained people purportedly describing “what happened” therein. Thus, many examples exist in social science research in which differing accounts are given for the same behavior or events; these are analogous to the differing accounts and descriptions of a sporting event provided by supporters of rival teams.

A third pitfall is the fact of observer differences. That is, apart from questions of bias in interpretation, observer differences lead to inevitable VARIANCE in data. For example, we encounter variance across observers in estimations of time intervals; frequency counts; or other, presumably objective characteristics of a behavior or event. Sometimes, this problem

can be remedied by having (and later averaging) observations provided by several judges or individual observers, each observing independently according to standardized instructions, and preferably not knowing each other's identity and not being familiar with the background or purpose of the research at hand.

A fourth pitfall of simple observation relates to the possibility of the observer's also being himself or herself a covert participant in the events being observed, sometimes with this participation remaining unknown to those whose behavior is being observed. Rosenhan (1973), for example, arranged for a team of PARTICIPANT OBSERVERS (“pseudopatients”) to be admitted separately and independently to a series of 12 different U.S. psychiatric hospitals, their admissions being unknown to the real patients and hospital staff. Such procedures have the benefit of gathering objective and factual observations (and inside information) about behavior in particular settings, in addition to other information more colored by interpretive bias or theoretical preference. Clearly, the procedures also bear ethical complications—to some degree, these represent a necessary cost that must be borne in exchange for being able to carry out ecologically valid observational research unaffected by participants' knowledge and awareness.

Observational procedures, especially when enhanced by permanent recording, thus have their greatest role in generating pure, immediate data in new or uncharted research areas. The RELIABILITY and interpretation of such data (and ideas generated therein for future research) can then be assessed, verified, and expanded upon in additional research.

SIMPLE RANDOM SAMPLING

Simple random sampling (SRS) is a special case of RANDOM SAMPLING. It involves selecting units by a

random chance mechanism, such that every unit has an equal and independent chance of being selected. Thus, the two features that distinguish SRS from other forms of random sampling are the equality and the independence of the selection probabilities. In consequence, each possible combination of n distinct units out of a population of N units will have the same chance of constituting the selected sample.

Selecting balls from a well-mixed bag is often considered a good approximation to SRS. Mechanisms that are constructed for the selection of lottery numbers are designed to be practically equivalent to SRS. Simple random sampling is rarely used for social surveys because there are typically good reasons to incorporate into the design features such as stratification (see STRATIFIED SAMPLE), clustering (see MULTISTAGE SAMPLING), and disproportionate sampling fractions (see SAMPLING FRACTION). However, it does provide a useful benchmark against which alternative sample designs can be compared, particularly in terms of BIAS and in terms of the VARIANCE of ESTIMATORS (see DESIGN EFFECTS).

Simple random sampling typically features heavily in sampling textbooks and courses because it provides a simple case for which the theory and algebra can be developed. This can then be extended to cover other, more realistic, sample designs.

SIMULATION

Most social science research either develops or uses some kind of theory or model; for instance, a theory of cognition or a model of the class system. Generally, such theories are stated in textual form, although sometimes, the theory is represented as an equation (e.g., in REGRESSION ANALYSIS). As personal computers became more common in the 1980s, researchers began to explore the possibilities of expressing theories as computer programs. The advantage is that social processes then can be simulated in the computer, and in some circumstances, it is even possible to carry out

experiments on artificial social systems that would be quite impossible or unethical to perform on human populations.

The earliest attempts to simulate social processes used paper and pencil (or card tiles on a checker board), but with the advent of powerful computers, more powerful computer languages, and the greater availability of data, there has been an increased interest in simulation as a method for developing and testing social theories.

The logic underlying the methodology of simulation is that a model is constructed (e.g., in the form of a computer program or a regression equation) through a process of abstraction from what are theorized to be the actually existing social processes. The model is then used to generate expected values, which are compared with empirical data. The main difference between statistical modeling and simulation is that the simulation model can itself be “run” to produce output, whereas a statistical model requires a statistical analysis program to generate expected values. As this description implies, simulation tends to imply a REALIST philosophy of science.

THE ADVANTAGES OF SIMULATION

To create a useful simulation model, its theoretical presuppositions need to have been thought through with great clarity. Every relationship to be modeled has to be specified exactly, and every parameter has to be given a value—otherwise, it will be impossible to run the simulation. This discipline means that it is impossible to be vague about what is being assumed. It also means that the model is potentially open to inspection by other researchers in all its detail. These benefits of clarity and precision also have disadvantages, however. Simulations of complex social processes involve the estimation of many parameters, and adequate data for making the estimates can be difficult to obtain.

Another benefit of simulation is that it can, in some circumstances, give insights into the “emergence” of macro-level phenomena from micro-level action. For example, a simulation of interacting individuals may reveal clear patterns of influence when examined on a societal scale. A simulation by Nowak and Latané (1994), for example, shows how simple rules about the way in which one individual influences another’s attitudes can yield results about attitude change at the level of a society, and a simulation by Axelrod (1995) demonstrates how patterns of political domination

can arise from a few rules followed by simulated nation-states. Schelling (1971) used a simulation to show that high degrees of residential segregation could occur even when individuals were prepared to have a majority of people of different ethnicity living in their neighborhood.

In this simulation, people's homes are represented by squares on a large grid. Each grid square is occupied by one simulated household (either a "black" or a "white" household) or is unoccupied. When the simulation is run, each simulated household in turn looks at its eight neighboring grid squares to see how many neighbors are of its own color and how many are of the other color. If the number of neighbors of the same color is not sufficiently high (e.g., if there are fewer than three neighbors of its own color), the household "moves" to a randomly chosen unoccupied square elsewhere on the grid. Then, the next household considers its neighbors and so on, until every household comes to rest at a spot where it is content with the balance of colors of its neighbors.

Schelling noted that when the simulation reaches a stopping point in which households no longer wish to move, there is always a pattern of clusters of adjacent households of the same color. He proposed that this simulation mimicked the behavior of whites fleeing from predominantly black neighborhoods, and he observed from his experiments with the simulation that even when whites were content to live in locations where there were a majority of black neighbors, the clustering still developed: Residential segregation could occur even when households were prepared to live among those of the other color.

AGENT-BASED SIMULATION

The field of social simulation has come to be dominated by an approach called *agent-based simulation* (also called *multiagent simulation*). Although other types of simulation, such as those based on system dynamics models (using sets of difference equations) and *MICROSIMULATION* (based on the simulated aging of a survey sample to learn about its characteristics in the future) are still undertaken, most simulation research now uses agents.

Agents are computer programs (or parts of programs) that are designed to act relatively autonomously within a simulated environment. An agent can represent an individual or an organization according to what is being modeled. Agents are generally

programmed to be able to "perceive" and "react" to their situation, pursue the goals they are given, and interact with other agents, for example, by sending them messages. Agents are generally created using an object-oriented programming language and are constructed using collections of condition-action rules.

Agent-based models have been used to investigate the bases of leadership, the functions of norms, the implications of environmental change on organizations, the effects of land-use planning constraints on populations, the evolution of language, and many other topics. Examples of current research can be found in the *Journal of Artificial Societies and Social Simulation*, available at <http://www.soc.surrey.ac.uk/JASSS/>.

Although most agent-based simulations have been created to model real social phenomena, it is also possible to model situations that could not exist in our world, in order to understand whether there are universal constraints on the possibility of social life (e.g., Can societies function if their members are entirely self-interested and rational?). These are at one end of a spectrum of simulations ranging from those of entirely imaginary societies to those that aim to reproduce specific settings in great detail.

A variant on agent-based modeling is to include people in place of some or all of the computational agents. This transforms the model into a type of multi-player computer game, which can be valuable for allowing the players to learn more about the dynamics of some social setting (e.g., business students can be given a game of this type in order to learn about the effects of business strategies). Such games are known as participatory simulations.

THE POTENTIAL OF SIMULATION

Although computer simulation can be regarded as simply another method for representing models of social processes, it encourages a theoretical perspective that emphasizes emergence, the search for simple regularities that give rise to complex phenomena, and an evolutionary view of the development of societies. This perspective has connections with complexity theory, an attempt to locate general principles applying to all systems and that show autonomous behavior—including not only human societies, but also biological and physical phenomena.

SIMULTANEOUS EQUATIONS

Many THEORIES specify relationships between variables that are more complicated than can be modeled in a single equation. Therefore, systems of simultaneous equations specify multiple equations, where each equation relates to the others. Possible relations include causal chains between DEPENDENT VARIABLES, RECIPROCAL RELATIONSHIPS between dependent variables, or CORRELATIONS between ERRORS in the equations. Simultaneous equation models can be considered a subset of STRUCTURAL EQUATION models that consider only observed variables.

Two major classes of simultaneous equations are RECURSIVE systems, where the direction of influence flows in a single direction, and NONRECURSIVE systems, where reciprocal causation, feedback loops, or correlations between errors exist. Simultaneous equation models can be specified in any of three ways: as a series of equations, as a PATH DIAGRAM, or with matrices of coefficients.

Equations in simultaneous equation systems are specified as in the following recursive simultaneous equation system:

$$y_1 = \gamma_{11}x_1 + u_1$$

$$y_2 = \beta_{21}y_1 + \gamma_{21}x_1 + \gamma_{22}x_2 + u_2$$

$$y_3 = \beta_{31}y_1 + \beta_{32}y_2 + \gamma_{32}x_2 + u_3$$

where $\text{COV}(u_1, u_2) = \text{COV}(u_1, u_3) = \text{COV}(u_2, u_3) = 0$.

In the system of equations, ENDOGENOUS VARIABLES are denoted with y s, and EXOGENOUS VARIABLES

are denoted with x s. β s indicate the effect of an endogenous variable on another endogenous variable, and γ s indicate the effect of an exogenous variable on an endogenous variable. The u s indicate errors in the equations.

After a model is specified, we must make sure it avoids the IDENTIFICATION PROBLEM. That is, we must establish whether the parameters of the model are estimable. A variety of rules and conditions to establish identification are available, including the null-beta rule, whereby models that do not have beta matrices, such as seemingly unrelated regression models, are identified; the recursive rule, which identifies all recursive models; the order condition; and the rank condition (see Bollen, 1989, pp. 98–103). Rigdon (1995) provides a straightforward way to identify many types of models that do not fall under the above rules.

Estimation of recursive systems of equations is straightforward and can be performed using ORDINARY LEAST SQUARES (OLS) regression on each equation. Estimation of nonrecursive systems of equations requires that estimation take account of the information from other equations in the system. Therefore, if OLS regression is applied to a nonrecursive simultaneous equation system, the estimates are likely to be BIASED and inconsistent. A variety of alternative estimation techniques are possible for nonrecursive simultaneous equation models, including two-stage least squares, three-stage least squares, and MAXIMUM LIKELIHOOD ESTIMATION. It is possible to view all of these estimators as INSTRUMENTAL VARIABLE estimators.

SKewed

A variable that has a skewed distribution is one that has most of its values clustered at the extreme end of a DISTRIBUTION of values for the variable. The measures

of CENTRAL TENDENCY for the variable are not equal. The consequences of skewness can be significant, especially for ORDINARY LEAST SQUARES (OLS) regression analysis.

To illustrate, envision a measure of democracy on a 0 (not democratic) to 100 (completely democratic) scale, constructed by making judgments about how well countries score on categories that fit a conceptualization of democracy (i.e., respect for civil rights and liberties, conducting free and fair elections). If the countries in the Northern Hemisphere are sampled, then the result will be that the OECD countries will cluster at the high democracy scores from 90–100. This is a negative skew on democracy, which means that the extreme values of the distribution are to the left of 90–100 along a continuum. If the countries in the Southern Hemisphere are sampled, where there are many more repressive dictatorships, then the result is that many countries will score at the 0–10 levels. This is a positive skew, meaning that the extreme values of the distribution are to the right of 0–10 along a continuum.

Extremely skewed distributions force social scientists to be cautious in interpreting statistical analyses, especially OLS regression. One of the OLS regression assumptions is that the INDEPENDENT VARIABLES have a linear relationship to the DEPENDENT VARIABLE. Another assumption is that the error term is distributed normally, which defaults in large samples ($N > 30$) to the dependent variable being distributed normally. Dependent variables with skewed distributions are likely to lead to a violation of the normality assumption. Independent variables with skewed distributions are unlikely to lead to a BLUE (BEST LINEAR UNBIASED ESTIMATION), at least if the sample is small.

The statistic for determining the skewness of any variable is as follows:

$$\text{Skewness of } y = \left\{ \sum [(y_i - \text{mean of } y)/s_y]^3 \right\} / N,$$

where $\sum$ = sum, s = standard deviation, and N = number of observations of the variable. The more NORMAL the distribution, the closer to zero the skewness statistic will be.

Remedies exist for skewness. Standard correction techniques involve arithmetic transformations of the variable. The most common transformation is a LOGARITHMIC transformation. It is effective in increasing the dispersion of a variable, breaking up clusters around a small number of values. Other transformations that

the analyst can try include a parabolic transformation, which involves squaring the variable, or a hyperbolic transformation, which is the operation $1/y$. In some instances, however, there is no practical remedy, and the researcher will simply have to live with a non-normally distributed variable.

SKEWNESS. See KURTOSIS

SLOPE

The equation for a straight line is $Y = A + BX$, where Y is the dependent variable, A is the y-intercept, B is the slope, and X is the independent variable. The slope is calculated by taking any two points on the line and dividing the rise by the run, where the run is the increase in X between the two points and the rise is the increase (or decrease) in Y between the two points (see Figure 1). A positive relationship between the two variables is indicated by a positive slope; a negative relationship is indicated by a negative slope.

When REGRESSION ANALYSIS is used in the social sciences, the data never fit perfectly along a straight line, meaning that we have error in prediction. The usual simple regression equation is $Y = A + BX + E$, where E represents the error associated with predicting Y given X . The slope is now interpreted as the average rate by which the dependent variable changes with a 1-unit change in the independent variable. In simple regression (i.e., where there is only one independent variable), the slope can tell us the marginal relationship between income and education. By way of an example, assume that we regress income (measured in dollars) on education (measured in years of schooling), obtaining a slope of 5000. We would argue, then, that an increase of one year of education is associated with, on average, an increase in income of \$5,000.

Figure 1 Diagram Depicting the Slope of a Straight Line

In MULTIPLE REGRESSION ANALYSIS (i.e., when there are several independent variables), the individual slope estimates for each independent variable pertain to partial relationships. In other words, each slope refers to the effect of a single independent variable on the dependent variable controlling for all other independent variables in the model. For example, assume that we regress income (again measured in dollars) on years of education and gender, obtaining a slope for education of 4000. The interpretation of the slope would then be the following: Holding gender constant, with every additional year of education, income increases, on average, by \$4,000.

Reporting the slope coefficients is usually sufficient when the functional form between two quantitative variables is linear because it is easily interpreted. If the functional form of the relationship between two variables is not linear (i.e., the slope of the regression line is not constant through the range of the independent variable), however, a single slope coefficient cannot summarize the relationship. In such cases, several slope estimates are needed, and graphs are usually required in order to fully comprehend the relationship. For example, in polynomial regression (see POLYNOMIAL EQUATION), the independent variable has one slope coefficient more than the number of changes in the direction of the line. In nonparametric regression (e.g., LOCAL REGRESSION), there are no slope coefficients, and the relationship can be displayed only in a graph.

The concept of slope can also be generalized to extensions of the linear model, such as GENERALIZED LINEAR MODELS and MULTILEVEL ANALYSIS. In nonlinear models such as LOGISTIC REGRESSION, slopes are usually best interpreted by calculating fitted probabilities.

SMOOTHING

Smoothing can be broadly considered a tool for summarizing or drawing out the important features of data. Such a useful tool has many applications in the analysis of data. Smoothing may be employed simply to create a HISTOGRAM that reveals more detail about the distribution of a CONTINUOUS variable in contrast to a histogram with bins. This same smoothing process is also used to create the FUNCTIONAL form of the DISTRIBUTION in NONPARAMETRIC estimation. When considering BIVARIATE relationships, smoothing is a valuable mechanism to discern the functional form of the relationship in the case of NONLINEARITY (see LOCAL REGRESSION). In TIME-SERIES analysis of a single variable (UNIVARIATE), smoothing may be performed during exploratory analysis to summarize the long-run changes in the variable. Smoothing is particularly useful for the FORECASTING of future values of a time series such as inflation or growth rates. Given an erratic distribution of data points, whether due to the WHITE NOISE component of a variable measured over time, abrupt changes in the density distribution of a variable, or a nonlinear bivariate relationship, smoothing techniques convey useful information by drawing out the systematic variation or the pattern of the data.

HISTOGRAM SMOOTHING

Smoothing of a histogram, rather than the use of bins, better reveals the particularities of a continuous variable's distribution. Bins suffer from the

disadvantages of concealing the continuity of the variable's distribution and possibly misrepresenting the data as a result of the arbitrariness of bin width and bin origin. As a routine analytical practice, smoothing permits better inspection of the distribution and evaluation of the NORMALITY assumption that may be made in the use of particular ESTIMATORS.

Given a non-normal distribution of continuous data, histogram smoothing is also used in nonparametric estimation to create the functional form of the distribution. Nonparametric estimation is often employed when there is reason to believe that the assumptions of parametric estimators are not satisfied, such as a non-normal distribution. Absent theoretical SPECIFICATION of the underlying distribution of the variable, the sample data provide the functional form of the distribution.

For both the routine analysis of a variable's distribution and the detection of the functional form of the distribution in nonparametric estimation, a smoothing technique obtains the best representation of the shape of the distribution. Essentially, for a variable X , smoothing utilizes the points close to any particular value of the variable x_i to create the density of the histogram. The degree of smoothing is positively related to the magnitude of the smoothing parameter (also known as the "bandwidth"). The smoothing parameter is the proportion of observations to which the smoothing operation is applied. A relatively small value of the smoothing parameter results in less smoothing because the observations relatively closer to x_i are weighted more heavily relative to observations further away. Conversely, a relatively large value of the smoothing parameter translates into greater smoothing as the weight given to close observations relative to further observations moves toward unity. Care should be taken to avoid "undersmoothing" or "oversmoothing" because the result is the introduction of BIAS. Undersmoothing, also known as "overfitting," occurs when excessive noise remains in the data so that the histogram does not reveal the meaningful features of the distribution. Oversmoothing, or "underfitting," refers to a histogram that conceals the important features of the data. A useful exercise is to experiment with various smoothing parameters, ensuring that the selected distribution is not highly sensitive to small changes in the magnitude of the smoothing parameter.

BIVARIATE OR SCATTERPLOT SMOOTHING

Smoothing is also useful in the inspection of the functional form of a bivariate relationship. Typically, a SCATTERPLOT is generated to detect the functional form of the bivariate relationship (LINEAR, CURVILINEAR, etc.). Unfortunately, the functional form is usually unclear. Smoothing the series of data points summarizes "how the central tendency of the Y variable's distribution changes at different locations within X 's distribution" (Jacoby, 1997, p. 63). As in the detection of the functional form of a single variable's distribution in nonparametric estimation, the purpose of smoothing a bivariate distribution is to allow the data to specify the functional form of the relationship. For a description of a common bivariate smoothing method, see the entry for LOCAL REGRESSION. Again, care should be taken to avoid oversmoothing or undersmoothing. Jacoby (1997) offers some useful strategies to avoid these errors. For example, a cluster of points through which the density line does not pass or remaining structure in the smoothed residuals indicates oversmoothing (or underfitting). Figure 1 provides examples of undersmoothing, oversmoothing, and a properly smoothed bivariate distribution (where, for a hypothetical class, X = grade in percent and Y = student evaluation of professor).

TIME-SERIES SMOOTHING

When smoothing the time series of a variable, the data are essentially treated as that part consisting of the true underlying pattern plus RESIDUAL noise, or the "smooth" plus the "rough." As with smoothing in general, the objective is to draw out the true underlying pattern of the time series without oversmoothing (when the variation of the underlying pattern of the time-series is lost to excessive smoothing) or undersmoothing (a time series that exhibits excessive noise so that the underlying pattern cannot be distinguished from the noise). In both cases, the underlying pattern is not easily discernible. Oversmoothing or undersmoothing is manifested in time-series forecasting by a large prediction error.

There are various smoothing techniques for univariate time-series data (Jacoby, 1997; Mills, 1990). In part, the desirable technique depends on the purpose of analysis. *Exponential smoothing*, for example, may be desirable for forecasting because this

Figure 1 Smoothing Examples

technique weights recent observations more heavily than distant observations. For exploratory purposes, a simple method such as *running medians* or *running weighted averages* may suffice. Essentially, these techniques smooth the time series by replacing each data point with the median or weighted average of close data points. The minimum order, or number of close data points used to adjust each observation, is 3. For example, the formula to determine the smoothed value of the data point x_t using running weighted averages with an order of 3 is the following:

$$s_t = (w_i)x_{t-1} + (w_i)x_t + (w_i)x_{t+1},$$

where s_t is the smoothed value and w_i is the weight assigned to each observation (symmetric around x_t). The application of this formula is then repeated for every x value. The appropriate order depends, in part, on the desired smoothing magnitude.

A greater degree of smoothing also may be achieved by using repeated iterations of the same smoothing technique or sequentially applying different smoothing techniques. Of course, the larger the order and/or the greater the number of smoothing treatments, the greater the susceptibility to oversmoothing.

SNOWBALL SAMPLING

Snowball sampling may be defined as a technique for gathering research subjects through the identification of an initial subject who is used to provide the names of other actors. These actors may themselves open possibilities for an expanding web of contact and inquiry. The strategy has been utilized primarily as a response to overcome the problems associated with understanding and SAMPLING concealed populations such as the deviant and the socially isolated (Faugier &

Sargeant, 1997). Snowball sampling can be placed within a wider set of methodologies that takes advantage of the social networks of identified respondents, which can be used to provide a researcher with an escalating set of potential contacts.

Snowball sampling is something of a misnomer for a technique that is conventionally associated more often with QUALITATIVE RESEARCH and acts as an expedient strategy to access hidden populations. The method has suffered an image problem in the social sciences given that it contradicts many of the assumptions underpinning conventional notions of random selection and representativeness. However, the technique offers advantages for accessing populations such as the deprived, the socially stigmatized, and the elite. In his study of political power and influence in South London, Saunders used a reputational method and asked his contacts to refer him to others who were viewed as holding power in the area (Saunders, 1979). This yielded important but also potentially self-contained systems of social contact but acted as a valuable insight into the perceptual basis of political power.

Snowball sampling has also advanced as a technique, and the literature contains evidence of a trend toward more sophisticated methods of sampling frame and error estimation and growing acceptance as a tool in the researcher's kit. Shaw, Bloor, Cormack, and Williamson (1996) illustrate these issues in their use of snowball sampling to estimate the prevalence of hard-to-find groups such as the homeless. Here, a technique viewed as a limited qualitative tool is highlighted as a systematic investigative procedure with new applications in the social sciences. However, although selection bias may be addressed through the generation of larger sample sizes and the REPLICATION of results, there also remain problems of gatekeeper BIAS, whereby contacts shield associates from the researcher. However, other groups may themselves consist of highly atomized and isolated individuals whose social network is relatively impaired, further problematizing contact with others.

Snowball sampling can be applied for two primary purposes: first, as an informal method to reach a target population where the aim of a study may be exploratory or novel in its use of the technique, and second, as a more formal methodology for making inferences with regard to a population of individuals that has been difficult to enumerate through the use of descending methodologies such as household surveys.

Early examples of the technique can be seen in classics such as Whyte's *Street Corner Society*, which used initial contacts to generate contexts and encounters that could be used to study the gang dynamic (although there has been a general move away from PARTICIPANT OBSERVATION of this kind toward the use of snowball sampling techniques for interview-based research more recently).

Although some have viewed snowball strategies as trivial or obscure, their main value lies as a method for dealing with the difficult problem of obtaining respondents where they are few in number or where higher levels of trust are required to initiate contact. Under these circumstances, such techniques of "chain referral" may imbue the researcher with characteristics associated with being an insider or group member, which can aid entry to settings in which conventional approaches have great difficulty.

SOCIAL DESIRABILITY BIAS

With regard to people's reports about themselves, social desirability is the tendency to respond to questions in a socially acceptable direction. This RESPONSE BIAS occurs mainly for items or questions that deal with personally or socially sensitive content. Social desirability is considered a personality variable along which individuals vary (Crowne & Marlowe, 1964), and it is only certain individuals who exhibit this bias. Crowne and Marlowe consider social desirability to be an indication of an individual's need for approval that results in a response bias rather than a response bias per se.

Social desirability as a personality variable is assessed most often with the Crowne and Marlowe (1964) social desirability scale. The scale consists of true/false questions about the self, each reflecting something that is either desirable or undesirable (e.g., "I always check out the qualifications of candidates before voting"). Considering the extreme wording "I always" or "I have never," it is almost impossible for more than a few of the items to literally be true of a person. Scoring high reflects the person's attempt, whether intentional or not, to put himself or herself in a favorable light and appear socially acceptable. Other scales also exist to assess social desirability. For example, the Paulhus (1984) scale assesses two dimensions of social desirability: other deception and self-deception.

Despite widespread concerns, there is little evidence to suggest that social desirability is a universal problem in research that relies on self-reports. For example, Moorman and Podsakoff (1992) studied the prevalence and effects of social desirability in organizational research. They concluded that relations tended to be quite small, and that social desirability produced little distortion of results among other variables. However, there are domains in which social desirability has been a potential problem, such as the area of psychological adjustment. This area is concerned with internal psychological states (e.g., anxiety and self-esteem) that are seen as socially desirable and can best be assessed through self-reports.

There are two approaches to dealing with social desirability. One is to design instruments and methods to reduce its impact on assessment. This might be accomplished through the careful choice of scale items that are not related to social desirability, which is possible for some but not all constructs of interest. The second is to assess social desirability independent of the other variables and then control for it. This could be done by eliminating from analysis individuals who score high on social desirability, or by STATISTICALLY CONTROLLING (partialing) the measure of social desirability from the other measures. This strategy can cause its own distortions, because one cannot be certain that relations of social desirability with other variables are due solely to BIAS or to real relations between the personality variable of approval need with the other variables of interest.

SOCIAL RELATIONS MODEL

The social relations model (Kenny & La Voie, 1984) is for dyadic or relational data from two-person interactions or group members' ratings of one another. Unlike SOCIOMETRY studies, the LEVEL OF MEASUREMENT is interval (e.g., 7-point scales) and not categorical (e.g., yes/no). Generally, the data are collected from people, but the units can be something else (e.g., organizations). The model can be viewed as a complex MULTILEVEL model.

The most common social relations design is the round-robin research design. In this design, each person interacts with or rates every other person in the group, and data are collected from both members of each dyad. Usually, there are multiple round robins. Other designs are possible. The minimum condition is that each person rate or interact with multiple others, and each person is interacted with or rated by multiple others.

There are three major types of effects in the social relations model. The actor effect represents a person's average level of a given behavior in the presence of a variety of partners. For example, Tom's actor effect on the variable of trust measures the extent to which he tends to trust others in general. The partner effect represents the average level of a response that a person elicits from a variety of partners. Tom's partner effect measures the extent to which other people tend to trust him. The relationship effect represents a person's behavior toward another individual, in particular, above and beyond the actor and partner effects. For example, Tom's relationship effect toward Mary on the variable of trust measures the extent to which he trusts her, controlling for his general tendency toward trusting others and her general tendency to be

trusted by others. Relationship effects are directional or asymmetric, such that Tom may trust Mary more or less than she trusts him. To differentiate relationship from error variance, multiple indicators of the construct, either across time or with different measures, are necessary.

The focus in social relations modeling is not on estimating the effects for specific people and relationships but in estimating the variance due to effects. So, for a study of how intelligent people see each other, the interest is in whether there is actor, partner, and relationship variance. Actor variance would assess if people saw others as similar in terms of intelligence, partner variance would assess whether people agree with each other in their ratings of intelligence, and relationship variance would assess the degree to which perceptions of intelligence are unique to the dyad.

The social relations model also permits a detailed study of reciprocity. For instance, it can be studied whether actors who tend to like others are liked by others (generalized reciprocity) and whether there is reciprocity of relationship effects (dyadic reciprocity).

There has been extensive research using the model. The most concentrated effort has been in the area of interpersonal perception (Kenny, 1994). Also investigated are the topics of reciprocity of disclosure, small-group process, and individual differences in judgmental accuracy.

SOCIOGRAM

A sociogram is the representation, through a graph, of relationships between individuals (or whatever the unit of analysis might be). Sociograms are helpful for mapping structures of relationships. They are usually the outcomes of research conducted under the umbrella of NETWORK ANALYSIS or SOCIOMETRY.

—Alan Bryman

SOCIOMETRY

This term is occasionally employed to refer to forms of measurement in the social sciences that are concerned with measurement through SCALES. Its more common use is in relation to an approach to research that emphasizes the mapping of relationships between units of analysis (individuals, groups, organizations, etc.). Increasingly, sociometry is called NETWORK ANALYSIS, and most research that was formally referred to as sociometric is subsumed by this field.

—Alan Bryman

SOFT SYSTEMS ANALYSIS

Soft systems analysis (SSA) is a method for investigating problems and planning changes in complex systems. It can also be used to design new systems. It was developed initially by Peter Checkland from Lancaster University (Checkland, 1981). The method can best be seen as a practical working tool, although it has been widely used in applied research. A core issue surrounds the meaning of “soft” as opposed to “hard” systems. The central idea in soft systems thinking is that people see and interpret the world differently. Discrepancies in the views held by individuals are not sources of invalidity or “noise” in the data; rather, differentiation reflects the nature of reality. Pluralism is the norm. In complex systems, individuals or groups are likely to construct quite different views of how the system works, what may be wrong with it, and how it should be improved.

Although recognizing that SSA can be used in a variety of ways, it is easiest to describe in its most straightforward format (Naughton, 1984). The method is organized in a series of relatively formal and well-structured stages through which its users work. In practice, considerable iteration can take place between the stages. The analyst initially gathers data about the problem situation (Stage 1), and this is represented in pictorial form (a “rich picture”) (Stage 2). The users of the method (i.e., the analyst and the system participants) then explicitly try looking at the system in a number of different ways, searching for views that add some new light (a “relevant system”) (Stage 3). They

select a new perspective on the problem situation and develop a conceptual model of what the system would logically have to do to meet the requirements of this new view (Stage 4). This model is then compared with the existing problem situation to see if there are any lessons for change (Stage 5). These are then discussed by the participants, who decide which should be implemented (Stage 6). Changes that are agreed to are then implemented (Stage 7). If the new view (from Stage 3) does not appear to offer help to the participants, another perspective is tried (i.e., the process returns to Stage 3).

An example helps illustrate key parts of the method. In this case, Symon and Clegg (1991) studied the implementation of a Computer Aided Design Computer Aided Manufacturing (CAD/CAM) system in a large aerospace company in the United Kingdom. The study was undertaken between 1988 and 1990, with a follow-up in 1996. After a period of intensive data gathering (Stages 1 and 2), the researchers argued that the company was utilizing an inappropriate (and very limited) view (or relevant system) of the implementation process, and offered a different one (Stage 3). The old relevant system saw the process as a straightforward technology implementation project, whereas the new one emphasized organizational change. A new conceptual model was generated, one required to meet the needs of this new view of the CAD/CAM implementation (Stage 4). The new model stressed the need to resource, plan, participate, educate, support, and evaluate. These needs were then matched against the actual implementation activities, and this helped identify some major gaps in practice. This led to the generation of a series of recommendations for action (Stage 5). After discussion (Stage 6), some of these were implemented by the company (Stage 7).

The researchers continued their work and further evaluated the impact of the CAD/CAM as it became more widespread in use, again matching practice against the conceptual model (from Stage 4). Further gaps were identified, and a second set of recommendations for action was made to the company (Stage 5). Again, some of these were agreed upon and implemented (Stages 6 and 7).

The follow-up study 6 years later revealed that the CAD/CAM implementation had been a success insofar as the technology was fully operational, widely used, and well liked. It was meeting most of its initial objectives. Various actions instigated by the researchers

(such as the formation of a CAD/CAM User Group) continued to function effectively. However, the CAD/CAM implementation had not achieved the level of integration between design and manufacturing that had been sought, in large part because the necessary structural changes between these two powerful functions had not been attempted.

As can be seen from this example, SSA has marked similarities to ACTION RESEARCH. In this case, we can see SSA as a particular instance of action research. However, action research includes a range of different approaches (e.g., survey feedback). Furthermore, some SSA change programs are more concerned with action than they are with research, and hence should not be labeled strictly as exemplars of action research.

SSA has a number of essential characteristics (Clegg & Walsh, 1998). It is highly participative, and it provides some structure and organization to the process of analyzing problems and planning change in complex systems. At various stages in the process, it actively promotes innovative thinking, and it requires careful analysis and logical modeling. With use, the method can be internalized, and, in our view, it can be a very useful addition to the skill set of people involved in research and development.

SOLOMON FOUR-GROUP DESIGN

The Solomon four-group design (Solomon, 1949) is a method used to assess the plausibility of PRETEST SENSITIZATION effects, that is, whether the mere act

of taking a pretest influences scores on subsequent administrations of the test. On a vocabulary test, for example, participants who were given a pretest might then decide to search a dictionary for a few unfamiliar words from that test. At posttest, they might then score better on the vocabulary tests compared to how they would have scored without the pretest. META-ANALYTIC results suggest that pretest sensitization does occur, although it is more prevalent for some kinds of measures than others, and is dependent on the length of time between pretest and posttest (Willson & Putnam, 1982).

In the Solomon four-group design, the researcher randomly assigns participants to one of four cells constructed from two fully crossed factors—treatment (e.g., TREATMENT or CONTROL GROUP) and whether or not a pretest is administered. Thus, the four cells are (a) treatment with pretest, (b) treatment without pretest, (c) control with pretest, and (d) control without pretest. The analysis then tests for whether treatment works better than control, whether groups receiving a pretest score differently from groups not receiving a pretest, and whether pretesting interacts with treatment effects.

The Solomon four-group design provides information relevant to both INTERNAL and EXTERNAL VALIDITY. Regarding internal validity, for example, many single-group QUASI-EXPERIMENTS use both pretests and posttests. If a pretest sensitization effect occurs, it could be mistaken for a treatment effect, so that scores could change from pretest to posttest even if the treatment had no effect at all. In randomized EXPERIMENTS, however, pretest sensitization effects do not affect internal validity because they are randomized over conditions, but those effects can be relevant to external validity if the size of the effect is dependent on whether or not a pretest is administered.

A computer literature search found 102 studies that reported using the design or a modified version of it, more than half of which (55) were published within the past 10 years. Many of those found no pretesting effect (e.g., Haight, Michel, & Hendrix, 1998). Dukes, Ullman, and Stein (1995) did find a pretesting effect on one of four DEPENDENT VARIABLES they used, resistance to peer pressure, suggesting potential lack of generalizability of the treatment effect when comparing groups with and without a pretest.

SORTING

In the method of sorting, respondents are presented with a set of objects and asked to divide the objects into a number of groups. As a method of data collection, sorting assumes that the researcher has chosen a specific area or domain and defined it by a list of instances (consisting of a word, phrase, photograph, picture, item, or actual object). These objects usually have been elicited previously by procedures such as free-listing or taxonomy construction. The respondent is presented with these objects, usually on a card, and asked to sort them into separate groups or piles (hence, pile-sorting) so that similar objects are put in the same group. The groups thus represent distinct categories or classes of the domain and together constitute a nominal scale.

The method of sorting is used especially in linguistics (to study the process of category formation) and in the study of perceptions of social and cultural worlds in order to see what significant categories and divisions

are used by participants. Sorting has the advantage that it can be used with large numbers of objects, and it is a task that respondents often report that they enjoyed doing.

VARIATIONS IN BASIC SORTING

In the basic form (free-sorting), any number of groups, of any size, may be formed. Restrictions imposed on the number and kind of groups define the variants of sorting:

- *Fixed sorting* occurs when there is a prespecified number of groups.
- *Graded sorting* occurs when groups are fixed in number and also ordered, as in a LIKERT SCALE.
- *Q-sort* occurs when, in addition to being fixed and ordered, the objects are required to follow a specified normal distribution across the groups.

Once the groups are formed, the respondent is invited to name and/or describe them, thus providing valuable interpretative data about the semantics of the categories.

More complex types of sorting include the following:

- *Multiple or successive sortings* (Boster, 1994), where respondents perform several sortings on the objects according to the same or different criteria
- *“Finer/coarser” sorting* (or GPA: Group-, Partition-, Additive-sorting) (Bimler & Kirkland, 1999), when the categories of the final sorting are (a) merged to form a grosser sorting, and (b) divided down to form a more detailed one. A very general form of sorting is the *agglomerative hierarchical sorting* (or *hierarchical clustering method*) (see Coxon, 1999), where respondents begin with each object in a single group (the “Splitter” partition) and form a set of successively more general sortings until all are in a single group (the “Lumper” partition)
- *Overlapping sorting*, where respondents may be permitted to allocate an object to more than one group, but in that case, conventional statistical methods cannot be used because the data no longer form a partition

ANALYSIS OF SORTING DATA

Once collected, sorting data can be analyzed in terms of the similarity of the *objects*, using co-occurrence measures (Burton, 1975) to measure how frequently a pair of objects occurs together in the respondents' groups, or the similarity of the *sortings* using minimum-move partition measures (Arabie & Boorman, 1973). These measures are represented using MULTIDIMENSIONAL SCALING and hierarchical clustering methods, and Takane (1981) has developed joint and three-way scaling models for these data.

SPARSE TABLE

A sparse table is a cross-classification of observations by two or more discrete variables that has many cells with small or zero frequencies. Sparse CONTINGENCY TABLES occur most often when the total number of observations is small relative to the number of cells. For example, consider a table with $N = 4$ cells and $n = 12$ observations. If the observations are spread evenly over the four cells, then the maximum possible frequency is small (i.e., $n/N = 3$). Furthermore, if the occurrence of observations in one of the four cells is a rare event, then a large sample would be needed to obtain observations in this cell. As a second example, consider a cross-classification of four variables, each

Table 1 Example of a Two-Way Table With Sampling Zeros

		<i>Genetic Testing: More Harm or Good?</i>			<i>Total</i>
		<i>More Good</i>	<i>More Harm</i>	<i>It Depends</i>	
<i>How Much</i>	<i>Great Deal</i>	54	10	0	64
<i>Know About</i>	<i>Not Very Much</i>	170	88	0	258
<i>Genetic Tests?</i>	<i>Nothing at All</i>	17	14	0	31
<i>Total</i>		241	112	0	353

with seven categories, which has $N = 7^4 = 2,401$ cells. A sample size considerably larger than 2,401 is required to ensure that all cells contain nonzero frequencies, and a much larger sample size is needed to ensure that all frequencies are large enough for statistical tests and modeling.

Sparseness invalidates standard statistic hypothesis tests, such as chi-square tests of independence or model goodness-of-fit. The justification for comparing test statistics (e.g., PEARSON'S CHI-SQUARE STATISTIC or the LIKELIHOOD RATIO STATISTIC) to a chi-square distribution depends critically on having "large" samples, where large means having EXPECTED VALUES for cells that are greater than or equal to 5. Without large samples, the probability distribution with which test statistics should be compared is unknown. Possible solutions to this problem include using an alternative statistic, performing exact tests, or approximating the probability distribution of test statistics by resampling or Monte Carlo methods.

Sparse tables often contain zero frequencies, which can cause estimation problems, including biased descriptive statistics (e.g., ODDS RATIO), the estimation of LOG-LINEAR MODEL parameters, and difficulties for computational algorithms that fit models to data. Whether an estimation problem exists depends on the pattern of zero frequencies in the data and the particular model being estimated. Parameters cannot be estimated when there are zeros in the corresponding margins. For example, Table 1 consists of the cross-classification of responses to the following two questions and possible responses from the 1996 General Social Survey (<http://www.icpsr.umich.edu:8080/GSS/homepage.htm>): (a) "Based on what you know, do you think genetic testing will do more good than harm?" with possible responses of "more good than harm," "more harm than good," and "it depends"; and (b) "How

much would you say that you have heard or read about genetic screening?" with possible responses of "a great deal," "not very much," and "nothing at all." None of the respondents answered "It depends" to the first question. For the independence log-linear model, a parameter for the marginal effect for "It depends" cannot be estimated. The information needed to estimate this parameter is the column marginal value, which has no observations.

In larger data sets, detecting a problem is more difficult. Signs of an estimation problem are extremely large estimates of standard errors or error messages on computer output such as "failure to converge." Solutions to estimation problems include adding parameters to a model so that the empty cells causing a problem are fit perfectly, adding a very small value to all cells of the table (e.g., 1×10^{-8}), or using an alternative estimation method. When empty cells exist because they are theoretically impossible (e.g., a man with menstrual problems), an extra parameter should be added to log-linear models for each empty cell. Adding parameters removes the cell from the analysis.

SPATIAL REGRESSION

Spatial REGRESSION analysis consists of specialized methods to handle complications that may arise when applying regression methods to spatial (geographic) data or to models of spatial interaction. There are

two broad classes of spatial effects. One is referred to as *spatial HETEROGENEITY* and occurs when the parameters of the model (regression coefficients, error variance); the functional form itself; or both are not stable across observations. This is a special case of structural instability and can be handled by means of the usual methods (modeling HETEROSKEDASTICITY, varying coefficients, random coefficients). It becomes *spatial* heterogeneity when the variability shows a spatial structure, which then can be exploited to model the heterogeneity more efficiently. For example, in the analysis of determinants of criminal violence, the southern states of the United States have been found to have different regression coefficients from the rest of the country. Because those states are geographically defined, this is referred to as a spatial regime, a special form of spatial heterogeneity.

The other form of spatial effects is referred to as *spatial dependence* (or *spatial AUTOCORRELATION*) and occurs when the error terms in the regression model are spatially correlated or when spatial interaction terms are included as explanatory variables in the regression specification. Spatial error autocorrelation is a special case of an error covariance matrix with nonzero off-diagonal elements. It is “spatial” when the pattern of nonzero elements follows from a model of spatial interaction. Typically, this involves a notion that neighbors are more correlated than locations further apart. For example, in real estate analysis, the sales price of a house is commonly considered to be determined in part by neighborhood effects. However, the latter cannot be quantified and therefore are incorporated in the regression error term. Because neighboring houses will be exposed to the same neighborhood effect, the regression errors will be spatially correlated.

The formal specification of the pattern of spatial correlation requires additional structure. There are two general ways in which this is pursued. In one, referred to as *geostatistical modeling*, the correlation between pairs of observations is expressed as a decreasing function of the distance that separates them. This is formally incorporated into the semivariogram in the field of geostatistics. In the other, referred to as *lattice* or *regional modeling*, the correlation follows from a spatial STOCHASTIC process, where the value of a random variable at a given location is expressed as a function of the other random variables at other locations through a spatial weights matrix. The spatial weights matrix is a positive matrix in which neighbors have a nonzero value (by convention, the diagonal elements are set to

zero). The definition of neighbors is perfectly general and need not be based on geographic considerations (e.g., social networks).

Apart from error correlation, spatial interaction can also be incorporated in the form of a spatially lagged dependent variable (or spatial lag), which is essentially a weighted average of the values for the dependent variable at neighboring locations. The resulting mixed regressive-spatial autoregressive model is the most commonly used specification for spatial externalities and spatial interaction in a cross-sectional setting. For examples, in models used in the study of local public finance, the tax rates set in one district may be expressed as a function of the rates in the neighboring districts (a spatially lagged dependent variable).

Ignoring spatial effects affects the properties of the ORDINARY LEAST SQUARES (OLS) ESTIMATOR. Ignoring a spatial lag renders OLS inconsistent, whereas ignoring a spatially correlated error term results in inefficient (but still unbiased) estimates. Specialized estimation methods have been developed, based on the maximum likelihood principle, instrumental variables, and general method of moments. Diagnostics for spatial autocorrelation are based on Moran's I autocorrelation statistic and applications of the Lagrange multiplier principle. Recent extensions include the incorporation of spatial correlation in models for latent variables and for count data, in the form of hierarchical specifications. Estimation of such models typically requires the application of SIMULATION estimators, such as the GIBBS SAMPLER.

8	9	64	81	72	1
9	12	81	144	108	9
17	10	289	100	170	49
11	8	121	64	88	9
12	11	144	121	132	1
13	13	169	169	169	0
14	15	196	225	210	1
15	14	225	196	210	1
16	20	256	400	320	16
10	18	100	324	180	64
18	16	324	256	288	4
19	19	361	361	361	0
20	17	400	289	340	9
$\sum X = 210$	$\sum Y = 210$	$\sum X^2 = 2,870$	$\sum Y^2 = 2,870$	$\sum XY = 2,768$	$\sum d^2 = 204$

$$r = \frac{2768 - \frac{210 \times 210}{20}}{\sqrt{2870 - \frac{210^2}{20}} \sqrt{2870 - \frac{210^2}{20}}} = 0.85$$

$$r_s = 1 - \frac{6 \sum d^2}{n^3 - n} = 1 - \frac{6 \times 204}{20^3 - 20} = 0.85$$

NOTE: The Pearson correlation coefficient (r) is applied and shown on the left-hand side. Note that both r and r_s reach the same conclusion.

(r_s) is one of the most widely used nonparametric correlation coefficients and gauges the relationship between two variables measured at the ordinal level. Suppose creativity (denoted X) and productivity (denoted Y) of n subordinates are evaluated by a manager. The manager assigns one of the ranks (i.e., $1, 2, \dots, n$) to all employees based on their creativity and productivity, respectively. Assuming there are no tied ranks on both variables, the relationship between creativity and productivity can be assessed by the Spearman correlation coefficient,

$$r_s = 1 - \frac{6 \sum d^2}{n^3 - n}$$

(where d is the difference between X and Y), which can actually be simplified from the formula for Pearson's correlation coefficient (Chen & Popovich, 2002).

A careful examination of the simplified formula reveals that the greater the difference between two variables across n subjects, the greater the value of $\sum d^2$ and the smaller the correlation coefficient. A fictitious example of 20 pianists' competition results is provided in Table 1. Each pianist is evaluated based on technical difficulty and artistic expression. Suppose a judge assigns ranks of 1 to 20 to each contestant on both performance categories, where rank 1 represents the highest performance. Assuming there are no tied ranks, the relationship between the two performance categories calculated by either the Spearman correlation coefficient or the Pearson correlation coefficient is 0.85. It should be emphasized that the above simplified formula cannot correctly calculate the Spearman correlation coefficient if tied ranks exist. The easiest way to calculate the

Table 2 Relationship Between Numbers of Annual Patent Applications and Quarterly Sales (in Millions)

<i>Organizations</i>	<i>Patent Application (X)</i>	<i>Quarterly Sales (Y)</i>	<i>Rank of X (RX)</i>	<i>Rank of Y (RY)</i>
A	20	5.60	5.0	6.5
B	9	1.10	2.0	1.0
C	50	6.60	9.0	9.0
D	33	7.20	8.0	10.0
E	17	4.30	3.0	4.0
F	25	5.60	6.0	6.5
G	79	6.30	10.0	8.0
H	5	2.90	1.0	2.0
I	27	4.90	7.0	5.0
J	19	3.70	4.0	3.0
Correlation	Pearson correlation coefficient based on the untransformed data (<i>X</i> and <i>Y</i>) is 0.68.		Spearman correlation coefficient based on the transformed data (<i>RX</i> and <i>RY</i>) is 0.89.	

NOTE: Organizations A and F are tied on quarterly sales. An average of rank 6 and rank 7, 6.5, is assigned to both organizations.

Spearman correlation coefficient is to apply the Pearson correlation coefficient whenever either tied or nontied ranks exist.

If the Spearman correlation coefficient is applied to variables measured on INTERVAL or RATIO scales, ranks of the variables need to be artificially assigned first. Numbers of annual patent applications (*X*) and quarterly sales (*Y*) of 10 organizations are presented in Table 2. Both variables are measured as ratio scales. Prior to applying the Spearman correlation coefficient, values of both variables should be transformed into ranks, where rank 10 represents the highest performance. Following this transformation, the Spearman correlation coefficient can be obtained with the same procedure described earlier. Note that tied ranks exist for the quarterly sales variable (Organizations A and F). Hence, the formula

$$r_s = 1 - \frac{6 \sum d^2}{n^3 - n}$$

is no longer appropriate, and the Spearman correlation should be obtained by the Pearson correlation coefficient formula. The magnitude of the Pearson correlation coefficient calculated based on the original values tends to be greater than that of the Spearman correlation coefficient calculated based on the transformed ranks, although the example provided here shows the exception.

The null hypothesis test of $\rho_s = 0$ can be conducted by

$$t = r_s \sqrt{\frac{n-2}{1-r_s^2}},$$

$df = n - 2$ when sample size is $19 \leq n < 30$. However, the test of $\rho_s = 0$ can be conducted more accurately by $z = r_s \sqrt{n-1}$ if $n > 35$ (Kendall & Gibbons, 1990). Exact critical values should be used when n is small for both formulas because the sampling distribution of r_s with a small sample size is not distributed as either the t or z distribution. When n is large, there is no apparent difference between both tests (Siegel & Castellan, 1988).

SPEARMAN-BROWN FORMULA

Developed independently by Charles Spearman (1910) and William Brown (1910), this formula

estimates the RELIABILITY of multi-item measures or INDEXES, and provides an important foundation for the statistical theory of measurement. The Spearman-Brown formula also calculates expected increases in reliability if more INDICATORS of the same trait are available. In both capacities, the Spearman-Brown formula is used frequently in the social sciences, especially in sociology, psychology, and education, where multi-item indexes are commonly employed.

To illustrate, following Brown (1910), let x_1 and x_2 be two measurements of a particular characteristic x , together comprising a “test” in which x_1 and x_2 are given equal weight. x'_1 and x'_2 are two other measurements of the same trait and, in combination, provide a parallel test of characteristic x . Suppose that all of the measurements are equally reliable, or that

$$\sigma_{x_1} = \sigma_{x_2} = \sigma_{x'_1} = \sigma_{x'_2} = \sigma_x,$$

where σ_{x_1} is the standard deviation of x_1 , and that their relationships to each other are comparable,

$$\sigma_{x_1x'_1} = \sigma_{x_1x'_2} = \sigma_{x_2x'_1} = \sigma_{x_2x'_2} = n\sigma_x^2r,$$

where $\sigma_{x_1x'_1}$ is the covariance of x_1 and x'_1 , r is a measure of reliability of each test, and n is the number of tests (in this case, $n = 2$). In practice, as Nunnally and Bernstein (1994) suggest, r might be the average CORRELATION across the group of observed measures (in this example, between x_1 and x_2) comprising a test. Then, the reliability of the indicator is estimated using an adjusted correlation coefficient, following Brown (1910):

$$\begin{aligned} r_{SB} &= \frac{\sigma_{(x_1+x_2)(x'_1+x'_2)}}{n\sigma_{(x_1+x_2)}\sigma_{(x'_1+x'_2)}} \\ &= \frac{\sigma_{x_1x'_1} + \sigma_{x_1x'_2} + \sigma_{x_2x'_1} + \sigma_{x_2x'_2}}{n(\sigma_{x_1}^2 + \sigma_{x_2}^2 + 2r\sigma_{x_1}\sigma_{x_2})} \\ &= \frac{4n\sigma_x^2r}{n(2\sigma_x^2 + 2r\sigma_x^2)} \\ &= \frac{4n\sigma_x^2r}{2n\sigma_x^2(1+r)} \\ &= \frac{2r}{1+r}. \end{aligned}$$

More generally, the Spearman-Brown coefficient may be calculated

$$r_{SB} = \frac{nr}{1 + (n-1)r},$$

where, as above, r is a measure of reliability (or average correlation among parallel tests) and n is the number of parallel tests.

To demonstrate, consider the following example: William H. Sewell (1942) was interested in developing a measure of the socioeconomic status of farm families. From an initial list of 123 items, Sewell constructed an index of 36 indicators he believed to measure a family's status. Then, dividing the items according to their numbering (even and odd) to construct two “half-tests,” Sewell estimated the correlation between them to be 0.83. Using the Spearman-Brown formula, Sewell adjusted this estimate of the correlation between the half-tests to generate an estimate of the reliability of his measure that takes the full test length into account:

$$\begin{aligned} r_{SB} &= \frac{nr}{1 + (n-1)r} \\ &= \frac{2(0.83)}{1 + (2-1)(0.83)} \\ &= 0.91. \end{aligned}$$

Because the Spearman-Brown coefficient is bounded by 0 and 1, where 1 indicates the highest possible level of reliability, Sewell was well satisfied by this result. If, however, Sewell was interested in increasing the reliability of his measure, the Spearman-Brown formula predicts gains in reliability that result from doubling the number of indicators, such that each half-test would now comprise one of four parallel tests (provided the original assumptions hold):

$$\begin{aligned} r_{SB} &= \frac{nr}{1 + (n-1)r} \\ &= \frac{4(0.83)}{1 + (4-1)(0.83)} \\ &= 0.95. \end{aligned}$$

Similarly, the Spearman-Brown “prophecy” formula can be used to estimate the number of indicators needed to achieve a desired level of reliability in a measure.

Analysts should note two assumptions made in the derivation of the Spearman-Brown formula: First, the expected values and variances of each measure are assumed to be equal across measures. Second, as stated above, covariances among all pairs of measures are assumed to be equivalent. In other words, the measures, on average, should generate the same mean scores, should be equally precise, and should

be equally related to each other. These assumptions, describing “classical parallelism” or an “exchangeable covariance structure” (Li, Rosenthal, & Rubin, 1996), are important because they allow analysts to estimate the reliability of an index with an adjusted measure of the correlation among its components. It seems, however, that these conditions rarely occur in the social sciences. Recognizing this, some researchers have provided generalized versions of the Spearman-Brown formula that readily incorporate measures with different levels of precision: In particular, Lee Cronbach, and G. Frederick Kuder and Marion Richardson, have built upon the important foundation laid by Spearman and Brown in the statistical theory of measurement; see CRONBACH’S ALPHA in this volume.

SPECIFICATION

Model specification refers to the description of the process by which the DEPENDENT VARIABLE is generated by the INDEPENDENT VARIABLES. Thus, it encompasses the choice of independent (and dependent) variables, as well as the functional form connecting the independent variables to the dependent variable. Specification can also include any ASSUMPTIONS about the STOCHASTIC component of the MODEL. Thus, specification occurs before ESTIMATION. A simple example of model specification with which most people are familiar is a model that assumes that some variable Y is a LINEAR FUNCTION of a RANDOM variable X and a stochastic disturbance term ε :

$$Y = \alpha + \beta X + \varepsilon. \quad (1)$$

There are many alternative specifications that would relate Y to X , such as

$$Y = \alpha + \beta X^2 + \varepsilon, \text{ or} \quad (2)$$

$$Y = \alpha + \beta X^3 + \varepsilon. \quad (3)$$

Once a model is specified, an estimation technique is merely a tool for determining the values of the PARAMETERS in the model that best fits the observed data to the specification. However, without correct model specification, any estimation exercise is merely curve-fitting without any ability to make valid STATISTICAL INFERENCES. To make inferences from the observed SAMPLE of data to the POPULATION, we are required to assume that all values of Y in the population are generated via the same process that generates the values in our observed sample. In other words, we must assume that the specification is correct. In the well-known GAUSS-MARKOV THEOREM, this is generally stated as “the model is correctly specified.”

Model specification should be based on some relevant THEORY. If the estimated parameters of the model are STATISTICALLY SIGNIFICANT, it may be regarded as confirmation of the theory. But in fact, it is technically a test of the model as specified versus the null model—a model that assumes there is no relationship between the dependent variable and the independent variables of the model. If we estimated any of the three models above and were able to reject the NULL HYPOTHESIS that $\beta = 0$ at the 95% level, we still could not say the specification we estimated was correct and the other two proposed specifications were incorrect.

Although infinitely many forms of *specification error* are possible, there are several common forms of specification error to beware of. Most ubiquitous is the problem of OMITTED VARIABLES. If the model specified omits an independent variable that is, in fact, part of the true model generating the data, then the model is misspecified. The consequences of this form of specification error are severe. Even in the simple case of ORDINARY LEAST SQUARES and a linear model, the estimated parameters of other variables may be BIASED, and we can make no valid statistical inferences.

There is no test to determine that we absolutely have the correct specification. However, we can often compare our specification to alternative specifications with statistical tests. The simplest tests involve specifications that are nested within one another. One specification is nested in another if it has identical functional form, but the variables in it are a subset

of the variables in the other specification. So, for instance, the model $Y = \alpha_0 + \beta_1 X_1 + \varepsilon$ is nested within the model $Y = \alpha_0 + \beta_1 X_1 + \beta_2 X_2 + \varepsilon$, but the model $Y = \alpha_0 + \beta_3 X_3 + \varepsilon$ is not tested in that model. Nested models are typically tested against one another using F TESTS of linear restrictions (or CHOW TESTS) for linear models, and log-likelihood ratio tests for MAXIMUM LIKELIHOOD models. Such tests are described in almost all econometrics texts. In both cases, one estimates each of two proposed models and generates a test statistic based on the fit of each model. A classical hypothesis test can then be performed that may let one reject one model in favor of another. In the case of an F test to compare two linear specifications, one of which is nested within another, the test statistic is given by

$$F = \frac{(R_{UR}^2 - R_R^2)/m}{(1 - R_{UR}^2)/(n - k)}, \quad (4)$$

which is distributed as an F statistic with DEGREES OF FREEDOM $(m, n - k)$, where m is the number of linear restrictions, n is the number of observations, and k is the total number of right-hand-side variables.

Non-nested specification tests are generally more difficult to perform. However, there are existing tests. The Cox test allows for a statistical test between two non-nested models. The Vuong test also allows for comparisons between non-nested models.

An alternative way to select between competing model specifications is by using model selection criteria. Model selection *criteria* do not provide a statistical test to prefer one model to another. However, they do provide agreed-upon criteria to choose one model over another. They are generally based upon a trade-off between GOODNESS OF FIT (all else being equal, we would prefer a model that explains more variance to one that explains less) and parsimony (almost all selection criteria penalize specifications for inclusion of additional variables). Commonly used criteria include the Akaike Information Criterion (AIC), Schwartz Criteria (SC), and Bayes Information Criteria (BIC). The AIC is simple to compute for linear models:

$$\text{AIC}(k) = e^{2k/n} \frac{\sum e_i^2}{n}. \quad (5)$$

Frequently, this is given in terms of its log:

$$\ln \text{AIC}(k) = \frac{2k}{n} + \ln \left(\frac{\sum e_i^2}{n} \right). \quad (6)$$

Those criteria are sensible, but ultimately involve arbitrary trade-offs. In the absence of a true statistical test, the researcher is not able to make any sort of probabilistic statement of how confident he or she is that he or she made the right choice among the models.

The assumption that we have the right specification is one of the most controversial in ECONOMETRICS. It led to Leamer's (1983) famous article "Let's Take the Con out of Econometrics," where he suggested dropping the assumption and instead examining virtually all sensible combinations of right-hand-side variables and reporting the bounds on the parameters. Because such bounds are generally large, this is not a suggestion that practitioners have adopted. But it does suggest that researchers test specifications for robustness to perturbations.

SPECTRAL ANALYSIS

Spectral analysis is one method of identifying the cyclical components of TIME-SERIES data. Cycles are periodic events typically represented as a waveform of the trigonometric sine or cosine function, or sinusoid, represented graphically and mathematically by Figure 1:

Figure 1 Spectral Analysis

where τ represents the period of the waveform, or the distance from one peak of the cycle to another; μ

represents the mean of the highest and lowest points of the waveform; ϕ represents the initial phase of the wave; and R represents the amplitude, or distance from peak to trough, of the waveform.

The sinusoid is an important component of cyclical analysis because it is used to MODEL the shape of those cycles. Where complex waveforms exist, researchers and statistical packages may model the cycles using several sinusoidal components. Although it is still possible to model the data if cycles deviate substantially from the sinusoid, such methods are mathematically complex and less tractable than the model presented here.

The cyclical nature of time-series data can be approximated once time TRENDS are removed from the data by partitioning the residual variance in a time series that is not due to a linear or CURVILINEAR trend in the data. The total SUM OF SQUARES is divided into a set of $N/2$ sum of squares components, each with 2 DEGREES OF FREEDOM. The estimates derived from the calculations are transformed into the sum of squares accounted for by each periodic component, to create intensity estimates.

In order to shrink the wide CONFIDENCE INTERVALS often associated with intensity estimates, spectral analysis smoothes the estimates to create a power spectrum. SMOOTHING procedures compute weighted averages of intensity estimates within a few neighboring frequencies. Variations in the number of neighboring frequencies (or width) included in the weighted average and variations in the weights applied, resulting from the use of different smoothing techniques, can produce more reliable estimates of the cyclical nature of the data. For instance, Daniell (equal weight) smoothing techniques with a width (or M) of 3 replace the intensity estimates for frequency i , with the mean for three ordinates, including $i - 1$, i , and $i + 1$. Equal weights (or $1/M$) are applied to the new estimates, $(1/3) \times \text{intensity at frequency } (i - 1) + (1/3) \times \text{intensity at frequency } i + (1/3) \times \text{intensity at frequency } (i + 1)$, to achieve a smoothed estimate of cycles. It is worth noting that the size of confidence intervals decreases as the number of neighboring frequencies increases. However, excessive smoothing can distort the data and make it difficult to make clear judgments about the lengths of cycles in the data (or τ).

Once the power spectrum is calculated, it is divided by the total amount of power or variance, producing a spectral density function. The results are typically

plotted with the spectral density on the y -axis and the frequency ($1/\tau$) on the x -axis. Data that exhibit a 4-year cycle would register a frequency of $1/4$ or .25 at its peak, which would be visible on a smoothed graph. Statistical significance is determined through the estimation of confidence intervals based on CHI-SQUARE DISTRIBUTIONS,

$$\text{Lower bound} = [edf^*s(f_1)]/X^2.99$$

$$\text{Upper bound} = [edf^*s(f_1)]/X^2.01,$$

where edf is the product of the original degrees of freedom prior to smoothing (2) and the width of the smoothing technique, and $s(f_1)$ denotes the spectral estimate for a given frequency. If confidence intervals overlap with the mean level of power (or mean of spectral estimates), then we might conclude that the peaks are not significantly different from what one might expect by chance. Alternatively, one could conduct a test of SIGNIFICANCE for unsmoothed peaks by dividing the largest sum of squares, or intensity estimate (sum of squares_{largest peak}), by the sum of the sum of squares total ($\sum$ sum of squares_{total}).

SPHERICITY ASSUMPTION

The sphericity assumption is necessary for statistical inference using univariate (or mixed-model) ANALYSIS OF VARIANCE on a WITHIN-SUBJECTS DESIGN. Informally stated, the sphericity assumption assumes that the VARIANCE of any linear combination of the repeated measures is identical. In particular, the differences between treatment levels have equal variance. If the assumption is not satisfied, it is necessary to either employ statistical corrections or else use MULTI-VARIATE ANALYSIS OF VARIANCES AND COVARIANCES.

An example clarifies the assumption. Suppose three individuals are exposed to three treatments producing the following data (and differences) (see Table 1):

Table 1

<i>Treat 1</i>	<i>Treat 2</i>	<i>Treat 3</i>	<i>1-2</i>	<i>1-3</i>	<i>2-3</i>
5	7	2	-2	3	5
3	7	4	-4	1	3
6	8	6	-2	0	2
Variance			1.33	2.33	2.33

In order to be justified in treating the data as a two-factor design (i.e., TWO-WAY ANOVA), the variances of the treatment differences must be identical. As the last three columns show, the sphericity assumption is not satisfied for the hypothetical example above because the variances of the differences are not identical. Note that if there are only two treatments, the sphericity assumption is satisfied by definition.

Incorrectly ignoring violations of the sphericity assumption results in a loss of statistical POWER OF A TEST. The actual probability of a TYPE I ERROR when the sphericity assumption is not satisfied is higher than standard calculations would imply. In other words, researchers risk making inferences that are unsupported by the data because the null hypothesis of no treatment differences will be rejected more often than it should (but by an unknown amount). Note that if the null hypothesis of no difference is not rejected, no correction is necessary because the nonadjusted test statistic is biased against this possibility.

If the sphericity assumption is not satisfied, the researcher has two options. First, one could try to adjust the test statistic to account for the violation. A number of adjustments are available and detailed elsewhere (e.g., Maxwell & Delaney, 1990). Alternatively, multivariate analysis of variances and covariances could be employed. Most recommend the use of multivariate methods unless sample sizes are very small.

SPLINE REGRESSION

Spline regressions are REGRESSION line segments that are joined together at special join points known as spline knots. By definition, there are no abrupt breaks in a splined line. However, at their knots, splines may suddenly change direction (i.e., SLOPE), or, for curved lines, there may be a more subtle, but just as sudden, change in the rate at which the slope is changing.

Splines are used instead of QUADRATIC, cubic, or higher-order POLYNOMIAL regression curves because splines are more flexible and are less prone to MULTICOLLINEARITY, which is the bane of polynomial regression. Spline regressions produce smoother lines than INTERRUPTED regression, which allows breaks, or jumps, in the line itself.

Splines are useful when a change in policy affects a line's slope without causing a break or gap in the line at the moment the policy change is introduced. For example, announcing an energy tax credit for more home insulation can reduce the slope of the energy consumption curve without causing a sudden drop in energy consumption. Tax schedules typically have tax brackets where the line representing the amount of tax paid as income rises does not change abruptly when passing from one tax bracket to another but instead changes slope at these spline knots.

Piecewise linear splines appear as straight lines with kinks in them. The kinks are the changes in slope at the knot locations. Define $D = 0$ when age is less than 21, so spline $D(\text{age}-21) = 0$ for ages 0 to 21. Define $D = 1$ for over 21, so $D(\text{age}-21) = 1, 2, 3, \dots$ for ages 22, 23, 24, etc. Thus, when age passes 21, the straight line rotates to a new slope at the kink (i.e., at the spline knot location) without causing a jump or break in the line.

Spline regressions are easiest to estimate when the number of spline knots and their locations are known in advance. Announced policy changes and tax brackets would be good examples. ORDINARY LEAST SQUARES can be used to easily estimate such spline regressions.

However, sometimes, the knot locations are not known exactly. For example, people's incomes typically rise as they get older, but then, on average, begin to decline after some unspecified point. Can this

point be ESTIMATED more precisely? The location of such an unknown spline knot can be estimated using NONLINEAR least squares.

What if the number of spline knots is unknown? STEPWISE REGRESSION can be used to search for the number and location of unknown spline knots. A list of potential spline knots is created in the form of variables available for possible inclusion in a regression. A particular spline knot is invited into the regression if its location and degree of adjustment (slope, rate of change of slope, etc.) provide the greatest degree of STATISTICAL SIGNIFICANCE among all of the specified spline knot candidates.

The spline variable might be time or some CROSS-SECTIONAL variable such as a person's age or the level of production. Splines can be used to estimate three-DIMENSIONAL surfaces. For example, after controlling for the variables on the multiple listing card (bedrooms, bathrooms, school district, etc.) a three-dimensional spline regression can be used to estimate the location value of a home.

SPLIT-HALF RELIABILITY

In classical test score theory, $X = T + e$ (where X = observed score, T = true score, and e = error). Some error is constant, reducing test validity, and some is variable, leading to inconsistency of scores. Reliability is the degree to which the test is free from variable error. Formally, given that $\sigma_x^2 = \sigma_t^2 + \sigma_e^2$, reliability is the ratio of true score variance to error score variance:

$$\sigma_t^2/\sigma_x^2 = (\sigma_x^2 - \sigma_e^2)/\sigma_x^2 \quad \text{or} \quad 1 - \sigma_e^2/\sigma_x^2.$$

Because they are necessarily a sample from the domain being measured, test items constitute one source of variable error. It can be estimated by comparing scores from two equivalent (alternate) forms of the test given at different times, but performance on the second test may be affected by the first one. Split-half reliability requires only one test administration, so participants are unaware of any comparison. It

is obtained by splitting the items into two equivalent sets and by correlating the pairs of scores (Pearson product-moment coefficient, r). Many kinds of split are possible, but some of them will not lead to equivalent sets. For example, item difficulty may vary between two sets selected at random and between two sets created from the first and second halves of the test. Scores on the two halves may also differ because of practice or fatigue, artificially lowering the split-half estimate.

Given that any split-half reliability value is not unique, at least two kinds should be calculated. There is even an algorithm for maximizing true reliability. However, the most popular technique is to group odd and even items. This overcomes fatigue and practice effects and equates the sets on difficulty if it increases throughout the test. Unfortunately, the odd/even split may not guarantee equivalence if different kinds of items are alternated, such as those requiring true/false or yes/no responses. The best method is to systematically create two equivalent sets by matching items according to content, difficulty, and kind of response (the parallel split). Means and variances of the two sets should be equal.

Because test reliability is a positive but decelerating function of the number of items, split-half r will underestimate full test reliability. Therefore, it is corrected with the SPEARMAN-BROWN prophecy formula $r' = 2r/(1 + r)$. Full test reliability can also be estimated directly with formulae such as Rulon's $r'' = 1 - \sigma_d^2/\sigma_x^2$ (where σ_d^2 is the variance of difference scores from the two parts of the test). Notably, this reflects the classic definition of reliability ($1 - \sigma_e^2/\sigma_x^2$, where $\sigma_e^2 = \sigma_d^2$). It yields the same value as the Spearman-Brown correction if $\sigma_1^2 = \sigma_2^2$ but is lower if $\sigma_1^2 \neq \sigma_2^2$.

Split-half reliability is not appropriate for tests that are highly speeded because people will score lower or higher on *both* sets, leading to a spuriously high correlation. It is also unsuitable for multidimensional tests because the different parts may be unrelated. However, it is a convenient technique for a homogeneous test. Although there are no universal standards for reliability, split-half (error from items within the test) should normally exceed .80, perhaps .85, and usually will be higher than TEST-RETEST (error from time) and ALTERNATE FORM (error from different items and time).

Example 1: A 24-item test taken by 148 people ($M = 11.20, s^2 = 20.20$) was divided into two sets

of 12 items. The means (5.38 and 5.89) and variances (7.12 and 5.57) for each set were not significantly different, indicating equivalent sets. The r between sets was .626, and the $s_d^2 = 4.81$. Using Spearman-Brown, $r' = 2(.626)/(1 + .626) = .770$. Using Rulon, $r'' = 1 - 4.81/20.20 = .762$. Both values indicate that split-half reliability is less than desirable.

Example 2: A 20-item test (5-point response scale) taken by 59 people ($M = 56.61$, $s^2 = 240.449$) was divided into odd and even items. The means (28.37 and 28.24) and variances (68.96 and 59.25) were not significantly different, indicating equivalent sets. The r between sets was .878 and $s_d^2 = 15.98$. Using Spearman-Brown, $r' = 2(.878)/(1 + .878) = .935$. Using Rulon, $r'' = 1 - 15.98/240.449 = .934$. Both values indicate that split-half reliability is very good.

SPLIT-PLOT DESIGN

A split-plot design is a research design in which units of the EXPERIMENT (e.g., consumers, parents, students) receive or are assigned to all treatments of one factor (say, Factor *B*) but only one treatment of the other factor (say, Factor *A*). In a split-plot design, Factor *A* is also called a “between-subjects” factor, whereas Factor *B* is called a “within-subjects” factor. For example, say one wishes to study the effect of Internet search strategies (Factor *A*) on college students’ information-seeking efficiency (the dependent variable) in two areas: health and history (levels of Factor *B*). One hundred freshmen at a state college are randomly selected and assigned to two conditions of Factor *A*: 50 students to the “linear search”

condition and the remaining 50 to the “nonlinear search” condition. All subjects are instructed to search for pertinent information on two topics chosen from health and history. The success of search is judged by three criteria: completeness, relevance, and speed. The following diagram illustrates the research design:

		Factor B: Topics			
		Subject	Health	History	Row Mean
Factor A: Internet Search Strategy	Treatment 1	S ₁	$\bar{Y}_{11}$	$\bar{Y}_{12}$	$\bar{Y}_{1.}$
	Linear	.			
	Search	.			
	Search	.			
	S ₅₀				
	Treatment 2	S ₅₁	$\bar{Y}_{21}$	$\bar{Y}_{22}$	$\bar{Y}_{2.}$
	NonLinear	.			
	Search	.			
	.	.			
	S ₁₀₀				
Column Mean			$\bar{Y}_{.1}$	$\bar{Y}_{.2}$	Grand Mean = $\bar{Y}_{..}$

In the diagram and research design, both Factors *A* and *B* are fully crossed. Because of the crossed nature of both factors, this design is technically a split-plot factorial (or SPF) design. Furthermore, an equal number of subjects are assigned to each condition of Factor *A*, which makes the design a balanced SPF design. Otherwise, it is an unbalanced SPF design. Because Factor *A* has two levels (linear search strategy vs. nonlinear search strategy) and Factor *B* also has two levels (health vs. history), this design is referred to in textbooks as an SPF_{2,2} design. The number of levels of a between-subjects factor is always written before the period (.), and the number of levels of a within-subjects factor is written after the period, both in the subscript. Variations of the split-plot design are in the form of more complex designs, such as the SPF_{pq,r} design, with two between-subjects factors and one within-subjects factor; the SPF_{p,qr} design, with one between-subjects factor and two within-subjects factors; the SPF_{pq,rt} design, with two between-subjects factors and two within-subjects factors; and so on. For details on these variations, readers should consult Kirk (1995) and Maxwell and Delaney (1990).

Notice that, in the SPF design above, subjects (denoted as S in the diagram) are embedded in a treatment condition of Factor *A* (or the between-subjects

factor) throughout the study. Consequently, an SPF design is also a nested design because subjects are considered nested within levels of Factor A (or the between-subjects factor). Furthermore, an SPF design is also a block design because subjects serve as their own controls in all levels of Factor B (or the within-subjects factor); hence, they are considered “blocks” according to the rationale of randomized block designs.

Split-plot design is one of the most popular research designs in social sciences. The design originated in agricultural research, in which parcels of land are called plots. Plots are subdivided into subplots in order to investigate the effect of fertilizers, soil conditions, and treatments of this sort. E. F. Lindquist (1953) popularized the use of this design in psychology and education and renamed it a MIXED DESIGN. The term *mixed design* reflects the unique mixture of the between-subjects factor and the within-subjects factor in the design. The split-plot design is also regarded as MODEL III design (Hays, 1994) in the sense that blocks (or subjects, in the example above) are usually treated as a random factor, whereas Factor A or B , or both, are a fixed factor. The inclusion of both random and fixed factors in the same SPF design dictates the statistical model, as stated below, to be a mixed model.

$$Y_{ijk} = \mu + \alpha_j + \pi_{i(j)} + \beta_k \\ + (\alpha\beta)_{jk} + \beta\pi_{ki(j)} + \varepsilon_{ijk}$$

$$(i = 1, \dots, n; j = 1, \dots, p; \text{ and } k = 1, \dots, q),$$

where

Y_{ijk}	is the score of the i th block (also the unit of observation and analysis) in the j th level of Factor A and k th level of Factor B .
μ	is the grand mean, therefore, a constant, of the population of all observations.
α_j	is the effect of the j th treatment condition of Factor A ; algebraically, it equals the deviation of the population mean (μ_j) from the grand mean (μ). It is a constant for all observations' dependent score in the j th condition, subject to the constraint that all α_j sum to zero across all treatment conditions of Factor A .
$\pi_{i(j)}$	is the population effect associated with each block i (i.e., subjects in the above diagram) nested within the j th condition of Factor A . Its underlying population distribution is assumed to be normal with equal variance in all blocks.

β_k	is the effect for the k th treatment condition of Factor B ; algebraically, it equals the deviation of the population mean ($\mu_{\cdot k}$) from the grand mean (μ). It is a constant for all subjects' dependent scores in the k th condition, subject to the constraint that all α_j sum to zero across all treatment conditions of Factor B .
$(\alpha\beta)_{jk}$	is the effect due to the combination of level j of Factor A and level k of Factor B . It is subject to the constraint that all $(\alpha\beta)_{jk}$ sum to zero across all treatment conditions of Factor A and Factor B .
$(\beta\pi)_{ki(j)}$	is the effect due to the combination of level k of Factor B and block i , both nested within the j th condition of Factor A . It is assumed that the underlying distribution of $(\beta\pi)_{ki(j)}$ is normal with equal variance across all blocks and all levels of Factor B . Furthermore, $(\beta\pi)_{ki(j)}$ is assumed to be statistically independent of the effect $\pi_{i(j)}$.
ε_{ijk}	is the random error effect associated with the i th block nested within the j th level of Factor A and crossed with the k th condition of Factor B . It is a random variable that is normally distributed in the underlying population and is independent of the effect $\pi_{i(j)}$.

To test statistical hypotheses concerning the effects of Factor A , Factor B , or A and B interaction, two error terms are needed. The first error term is used in testing the between-subjects factor (i.e., A) and is computed from the average of (two, in the example above) mean squares within A levels by ignoring Factor B . The second error term is used in testing within-subjects factor (i.e., B) and its interaction with the between-subjects factor (i.e., A by B). It is computed from the average of (four, in this example) mean squares within the A by B combinations. Technically, it is the pooled interaction of Factor B and the blocks (i.e., subjects, in this example) that are subsumed under each level of Factor A . All statistical tests are performed by the F statistic under the assumption of homogeneity of variance. The F tests of the within-subjects factor and its interaction with the between-subjects factor require an additional assumption, namely, the sphericity assumption for the variance and covariance matrix of the within-subjects scores. The sphericity assumption is the necessary and sufficient condition for the validity of the F test (Huynh & Feldt, 1970).

SPURIOUS RELATIONSHIP

A spurious relationship implies that although two or more variables are correlated, these variables are not causally related. CORRELATION analysis merely establishes covariation, the extent to which two or more phenomena vary together, whereas CAUSATION concludes that one phenomenon caused another. Although social scientists are interested in correlation, most would also like to infer causality. For example, although we know that smoking is related to lung cancer, we want to infer the possibility that smoking causes lung cancer. But when seeking inferences of causality, social scientists must beware the possibility of spurious relationships, which falsely imply causation.

Suppose we are estimating a coefficient of correlation r_{xy} , where x is the marital status of an individual and y is the amount of wine consumed annually by that individual. We find a high positive correlation between marital status and wine consumption. If we infer a causal relationship, we may posit that consuming wine causes people to get married. We may also posit that marriage drives individuals to drink wine. Logically, neither of these interpretations makes sense. It is more likely that the relationship between wine consumption and marriage is spurious, and a third variable is causing positive correlation in both variables.

Spurious correlation means that the relationship between two variables disappears when a third variable is introduced. Theory or logic should specify a third variable that may account for the observed correlation between the variables of interest. In the example above, we suspect that variable z , age, may have a joint effect on both marital status and wine consumption. We find a high positive correlation, r_{xz} , between marital status and age, and a high positive correlation, r_{yz} , between wine consumption and age. These strong correlations offer initial evidence that variation in age accounts for the relationship between marital status and wine consumption. To test for spuriousness, we calculate $r_{xy \cdot z}$, the PARTIAL CORRELATION COEFFICIENT between marital status and wine consumption, which CONTROLS for age, where $r_{xy \cdot z} = r_{xz} * r_{yz}$. We find that $r_{xy \cdot z}$

does not significantly differ from zero, meaning that the relationship between marital status and wine consumption disappears when controlling for age. We thus speculate that the correlation between marital status and wine consumption results from the joint effect of variation in age. In other words, the relationship between marital status and wine consumption could be spurious.

Because the value for $r_{xy \cdot z}$ does not significantly differ from zero, we might also conclude that z is a MEDIATING VARIABLE between x and y . In the above example, this would imply that marriage leads to aging, and becoming older leads to more wine consumption. For our example, this is a nonsensical conclusion, but in other cases, the distinction may not be clear. It is up to the researcher to make logical assumptions about the direction of causation and to use those assumptions to conclude if x and y are spuriously related, or if z is a mediating variable. Statistical evidence alone cannot distinguish between these two possibilities.

STABILITY COEFFICIENT

Stability coefficient is a term that, in the social sciences, means the correlation of measurement results from Time 1 with measurement results from Time 2, where the subjects being measured and the measuring instrument remain precisely the same. If the coefficient is high (and no instrument reactivity is present), it generally signals both measurement RELIABILITY and response continuity. If it is low, a correct interpretation is harder to reach.

A low stability coefficient with measures of personal history or behavior plainly derives from unreliability. If respondents first report and then later deny features of personal background or past conduct, one does not interpret the change as “discontinuity.” However, with attitudes and opinions, the low coefficient is of less certain meaning. It is not uncommon for such a

coefficient to be treated as an indicator of unreliability when the test-retest interval is short (Carmines & Zeller, 1979; Litwin, 1995) but as an indicator of attitudinal discontinuity when that interval is long (Converse & Markus, 1979). Neither of these two interpretations is self-evidently correct, and disentangling the reliability and continuity components of a stability coefficient can be complicated and important (Achen, 1975). Indeed, an accurate estimate of continuity cannot be determined without knowing, and correcting for, the level of measurement unreliability.

A TEST-RETEST time interval of days or weeks obviously strengthens the assumption that low stability is caused by measurement problems rather than attitude change. Even here, however, other factors may intervene. For example, in turbulent times, there may be considerable short-term shuffling of true opinions. And whether the times be turbulent or peaceful, accurately stated opinions on unfamiliar or ill-considered topics also may show substantial short-run instability. Attitudinal ephemera do not represent true measurement error, although if one embraces a definition of “attitude” that emphasizes its enduring nature, such ephemera may be regarded as “nonattitudes.”

The use of CORRELATION coefficients, whether product-moment or rank-order, in estimating continuity may sometimes be problematic. With either standardized or ranked data, there can be systematic change between Time 1 and Time 2 that is not reflected in the correlations. Response distributions may shift upward or downward or may tighten or spread, and stability coefficients nonetheless remain high. For that reason, it is important to look further into the correlation, inspecting scatter diagrams with interval data or contingency tables with ranked data, for signs of such distributional changes.

STABLE POPULATION MODEL

What are the long-term implications of the maintenance of current demographic patterns over a long period? Alfred Lotka's extension of biological models of population renewal to the domain of age-specific rates provides many of these answers (Lotka, 1939/1998). A stable population, having constant birth rates and age distribution, emerges when the following three characteristics, which closely approximate the long-term conditions of many historic populations, persist over the long term:

1. Age-specific fertility rates are constant.
2. Age-specific death rates (i.e., the LIFE TABLE) are constant.
3. Age-specific net migration rates are zero.

The simple demographic properties underlying stable populations form the basis of population projections and the analysis of demographic components (age distribution, mortality, and fertility). Of particular importance is the property of *ergodicity*, which states that the long-term age distributions, birth rates, death rates, and growth rates of stable populations are determined by their current fertility and mortality schedules irrespective of current age distributions.

The long-term size, population distribution, and vital rates of a stable equivalent population can be predicted from current vital rates (see DEMOGRAPHIC METHODS for more). The proportion of the population at each age (${}_nK_x^{\text{stable}}$) can be represented in terms of life table survival functions (${}_nL_x$), births (B), and population growth (r)

$${}_nK_x^{\text{stable}} = B {}_nL_x e^{-r \cdot x}.$$

The total number of births, B , varies according to the initial population age distribution, yet long-term crude birth rates and yearly growth in the number of births are functions only of fertility and women's mortality schedules. The *intrinsic growth rate*, r , or the stable growth rate implied by current vital rates, bears a direct and easily estimated relationship to the Net Reproduction Rate (NRR), the average number of girls produced by each woman based on current birth and death rates:

$$\text{NRR} = e^{rT},$$

where T is the mean length of a generation.

Figure 1 depicts the stabilization process through a simple hypothetical population projection (see LESLIE'S MATRIX). Italy's vital rates from 1995, characterized by low fertility and low mortality, are used to project forward the 1995 age distributions of Italy (a relatively aged society) and Nigeria (a young society). Their age distributions differ dramatically over the medium term (2030–2060), as large cohorts of very young Nigerians age into their childbearing years, producing relatively large cohorts of children in spite of low fertility rates. Over the long term (2100–2200), the age distributions grow statistically identical, as the ripple effects of earlier cohorts in both populations diminish.

Although their age distributions are identical by 2200, Nigeria's overall population growth would have been much greater. The stable population model can be applied to the measurement of *population momentum*, the population growth and temporary demographic changes emerging when fertility decline occurs in a population with a young age distribution (Keyfitz, 1985). Although Nigeria's population would have grown substantially more than Italy's as its largest ever cohorts aged into childbearing, all of this growth would have occurred at ages above the mean age of childbearing; new cohorts could only be smaller than old cohorts given such low fertility rates.

Simplified demographic accounting procedures stemming from the stable population model have led to a greater empirical understanding of the complex medium- and long-term implications of demographic change. In particular, family planning strategies have been influenced by the substantial impact of *delayed* childbearing on future population size (e.g., "later, longer, fewer") through associated increases in the mean age of childbearing. Government pension schemes have been influenced by the greater relative impact of fertility decline, vis-à-vis mortality decline, on population aging and old-age dependency (the relative number of elders compared to young adults), and the cyclical economic effects of rapid population aging as large cohorts age from childhood dependency, to adult productivity, to old-age dependency.

Further methodological innovations have stemmed from relaxing key assumptions of the stable population model. The *variable- r method* generalizes the properties of stable populations to nonstable populations, facilitating a wide range of demographic projection and correction techniques (Preston & Coale, 1982). Generalization of the stable model to populations

Figure 1 Relative Age Distributions for Italy and Nigeria, Both Projected Using Vital Rates for Italy, 1995
 SOURCE: Adapted from Preston, Heuveline, and Guillot (2001) and United Nations (1995, 1996).

with constant, nonzero, age-specific migration rates facilitated the development of multistate and multi-regional stable population models (Rogers, 1995).

For further discussion and examples, see Preston et al. (2001).

STANDARD DEVIATION

One of the primary properties of a set of numbers or scores is its variability or DISPERSION—how much the scores differ from one another. Probably the most commonly used measure of the variability of a set of scores is the standard deviation. It is popular both because it takes into account the exact numerical value of every score and because it is defined in the units of the scores themselves. That is, if heights are measured in inches, the standard deviation is also expressed in inches.

Most often, the standard deviation is considered as a supplement to measures of average, such as the arithmetic MEAN. For example, many cities have

similar mean temperatures for the year, but they differ widely in variability of temperatures across seasons. In describing and comparing the weather in these cities, it would be informative to classify them in terms of variations in temperature across the year as well as overall yearly average temperature.

Similarly, in research designed to generate appropriate inferences about human behavior, standard deviations can be as important as means. Consider, for example, a program designed to increase students' test performance. To be sure, you'll be looking for an increase in average scores following the program. However, this increase could come in several forms. If the program helped each student to approximately the same degree, the mean scores would increase from before to after the program, but the standard deviations would be about the same. If, however, the program helped only the best students while leaving the rest unchanged, you would still get an increase in mean but also an increase in standard deviation (i.e., a greater separation of the best and worst students). For some educators, this latter result would not be considered as desirable as would be evident from inspection of means alone. The increased standard deviation would serve as an important clue as to how the program affected scores.

The standard deviation of a complete set or population of scores, σ , is defined as the square root of the sum of the squared differences between each score X and the mean of the scores, μ , divided by the number of scores N ; that is,

$$\sigma = \sqrt{\frac{\sum (X - \mu)^2}{N}}.$$

Squared differences are used because otherwise, the positive and negative differences would cancel each other. Without the square root, the measure σ^2 is called the VARIANCE, but it is expressed in units squared (e.g., square inches) rather than the units themselves. In computing the standard deviation of a sample of scores, s , as an estimate of the population standard deviation, a slight correction is made in the formula:

$$s = \sqrt{\frac{\sum (X - \bar{X})^2}{N - 1}},$$

where $\bar{X}$ is the mean of the sample of scores and N is replaced by $N - 1$. This corrects for an overall bias to underestimate the population

standard deviation based on data from a sample. A "computational" form of the same equation is the following:

$$s = \frac{\sum X^2 - [(\sum X)^2 / N]}{N - 1}.$$

To illustrate, consider the following sample of 10 scores:

8, 26, 15, 9, 13, 20, 21, 10, 15, 12.

For these scores, $\sum X = 149$; $(\sum X)^2 = 22,201$; $\sum X^2 = 2,525$; and $s = 5.82$. A good summary of this sample of 10 scores is that it has a mean of 14.90 and a standard deviation of 5.82. Without the standard deviation, this description would be incomplete.

—Irwin P. Levin

STANDARD ERROR

The standard error of a STATISTIC is the STANDARD DEVIATION of the SAMPLING DISTRIBUTION of the statistic, and it is used to measure the RANDOM VARIATION of that statistic around the PARAMETER that it estimates. For example, the standard error of a MEAN is the standard deviation of a DISTRIBUTION of means for an infinite number of samples of a given size n . The size of the standard error is dependent, in part, upon the sample size, and in accordance with the Law of Large Numbers, as sample size increases, the standard error decreases. In addition, if a statistic is an UNBIASED ESTIMATOR of its parameter, the larger the sample size, the more closely the statistics will cluster around the parameter.

The true standard error of a statistic is generally unknown, and the term *standard error* commonly refers to an estimate. Although standard errors can be estimated from a FREQUENCY DISTRIBUTION by repeated sampling, usually they are estimated from a single sample and represent the expected standard deviation of a statistic as if a large number of such samples had been obtained. Estimates of standard errors from a single sample are possible because the properties of the sampling distributions for certain statistics have already been established. Methods for estimating a standard error from a single sample are demonstrated

below for two statistics: a sample mean, $\bar{X}$, and a REGRESSION COEFFICIENT, $\hat{\beta}_1$.

THE STANDARD ERROR OF A SAMPLE MEAN, $\bar{X}$

The CENTRAL LIMIT THEOREM establishes that the sampling distribution of $\bar{X}$ is normally distributed if the sample was drawn from a population that is itself normally distributed, even if the sample size is small. Furthermore, if the sample size is large, the sampling distribution of $\bar{X}$ is normally distributed, even if the population is not normally distributed. Thus, given the central limit theorem, virtually every $\bar{X}$ is assumed to have a sampling distribution that is normally distributed, and because $\bar{X}$ is an unbiased estimator of the population mean μ , the mean of the sampling distribution is equal to μ , and the standard error, $\sigma_{\bar{X}}$, is equal to the population standard deviation of X , σ , divided by the square root of the sample size:

$$\sigma_{\bar{X}} = \frac{\sigma}{\sqrt{n}}.$$

When the population standard deviation is unknown, as is generally the case, the standard error is estimated using the sample standard deviation, s , or

$$s_{\bar{X}} = \frac{s}{\sqrt{n}}.$$

In other words, $\sigma_{\bar{X}}$ is the standard error of $\bar{X}$, and $s_{\bar{X}}$ is the estimated standard error of $\bar{X}$.

THE STANDARD ERROR OF A REGRESSION COEFFICIENT, $\hat{\beta}_1$

If the DEPENDENT VARIABLE (Y) in a REGRESSION model is drawn from a sample of normally distributed observations that are independent and identically distributed, ORDINARY LEAST SQUARES estimates of the parameters have normally distributed sampling distributions. In a simple regression model with only one INDEPENDENT VARIABLE, $Y = \beta_0 + \beta_1 X + \varepsilon$, the estimate of β_1 is denoted $\hat{\beta}_1$. The sampling distribution of $\hat{\beta}_1$ is normally distributed with mean equal to the parameter β_1 and estimated variance $s_{\hat{\beta}_1}^2$ equal to the estimated variance of the RANDOM ERROR term s^2 divided by the sum of the squared deviations of X . Thus, the estimated standard error of $\hat{\beta}_1$ is the square root of $s_{\hat{\beta}_1}^2$, or

$$s_{\hat{\beta}_1} = \sqrt{\frac{s^2}{\sum (X - \bar{X})^2}}.$$

The numerator indicates that the standard error of $\hat{\beta}_1$ is smaller when the error variance is smaller, and the denominator indicates that more variance in X results in a smaller standard error of $\hat{\beta}_1$, or a more precise estimator.

STANDARD ERROR OF THE ESTIMATE

The standard error of the estimate (SEE) is, roughly speaking, the average “mistake” made in predicting values of the DEPENDENT VARIABLE (Y) from the estimated regression line. The SEE is assumed to be constant over all values of X . Thus, the average error in predicting Y when $X = x_i$ and $X = x_j$, $x_i \neq x_j$, will be the same. This is implied by the assumption of constant error variance [$\text{Var}(u_i|X_i) = \sigma^2$] in the classical linear regression model (CLRM).

There is an intuitive similarity between the SEE and the STANDARD DEVIATION of a RANDOM VARIABLE. The standard deviation of a random variable is nothing more than the square root of the average squared deviations from its MEAN. Similarly, the SEE is the square root of the average squared deviations from the regression line. Within a regression framework, these deviations are represented by the DISTURBANCE TERMS [$\hat{u}_i = (y_i - \hat{y}_i)$]. Thus, the SEE can be understood as the standard deviation of the SAMPLING DISTRIBUTION of disturbance terms, which, by assumption, is centered on zero. The SEE is also known as the root MEAN SQUARE ERROR of the regression.

For a regression in which k parameters are estimated, where k is taken to be the number of independent variables in the regression model plus the constant, the SEE is given by the following:

$$\hat{\sigma} = \sqrt{\frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{n - k}}.$$

The SEE is a measure of the GOODNESS OF FIT of the estimated REGRESSION line to the data. The smaller the SEE, the better the regression line fits the data. If the regression line fits the data perfectly, then each observation in the data set will fall exactly on the regression line and the SEE will be zero. Some researchers consider the SEE to be the preferred measure of fit of a regression model, and the statistic has many advantages. First, it is expressed in units of the dependent variable allowing for meaningful comparisons across regressions with the same dependent variable. Also, it is not dependent on the VARIANCE of the INDEPENDENT VARIABLES in the model as is another commonly used measure of fit, R^2 .

To see how the SEE is calculated, consider an example. An instructor is interested in predicting student performance in an introductory statistics class. The instructor believes that students' final exam grades are a LINEAR additive function of the following independent variables: (a) GPA, (b) SAT, (c) Gender, and (d) Year in School. Using a RANDOM SAMPLE of 15 students, the instructor generates the following PREDICTION EQUATION:

$$\hat{Y}_i = 9.14 + 1.78GPA + 0.11SAT \\ - 2.67GENDER + 2.10YEAR.$$

These estimates are then used to generate predicted values on Y for each of the students sampled (see Table 1).

How well does the estimated regression line fit the observed data? To answer this question, the instructor calculates the SEE. Using the data in Table 1 and the formula given above the SEE,

$$\hat{\sigma} = \sqrt{\frac{144.69}{15 - 5}} = \sqrt{14.47} = 3.80.$$

On average, the model will make a prediction error of 3.80 points. Recalling that a small standard error is associated with a better fit (and noting that the standard deviation of Y is 9.68), we would conclude that the estimated regression line fits the data in this example well.

STANDARD SCORES

Standard scores enable us to more readily understand the meaning of a particular score. For example, knowing that a student answered 20 items correctly on a 30-item math test gives us only a very rough view of that student's performance. It is hard to know how good or bad this score is without knowing how other students at the same grade level scored. We would know more if we were told that the mean score for all other students at the same grade level taking the exam under the same circumstances was 17. We would at least know that our student was "somewhat above average." If we were also told that the scores had a standard deviation of 3, we would have a better idea of "how much above average," namely, one standard deviation above the mean. Suppose we learned that the same student answered 35 items correctly on a 50-item test of verbal ability where the mean was 40 and the standard deviation was 5. We would then know that

this same student scored one standard deviation below the mean on the verbal test.

As illustrated in the above example, standardizing sets of test scores by adjusting each score to the mean and STANDARD DEVIATION of the set serves the following two important functions: (a) It allows us to relate one student's test score to the complete set of scores for all comparable students, and (b) it allows us to compare the score on one test to the score on another test for the same student. The latter can be particularly useful in identifying a student's relative strengths and weaknesses.

There are a variety of ways of forming standard scores. For example, some personality measures are adjusted such that the mean will be 50 and the standard deviation 10, and some intelligence tests are scored such that the mean will be 100 and the standard deviation 15. The most common form of standard score used by social scientists, however, is the Z-SCORE, which transforms each score X by subtracting the mean of the scores, $\bar{X}$, and dividing the difference by the standard deviation, s : $z = (X - \bar{X})/s$.

Each TRANSFORMED score then directly represents how many standard deviations above or below the mean that score is. $z = +1$ means the score is one standard deviation above the mean, $z = -1$ means one standard deviation below the mean, $z = 0$ means that that score falls at the exact arithmetic mean, and so forth. When the form of the original distribution of scores is known, these standard scores can be further translated into PERCENTILES. For example, in a NORMAL DISTRIBUTION, only 16% of the scores are more than one standard deviation above the mean, so a z -score of $+1$ falls at the 84th percentile. (Most statistics books include a table for translating standard scores in a normal distribution into percentiles.)

Another useful property of z -scores and other standard scores formed by adjusting for the mean and standard deviation is that they are unit-free. For example, a person's standard score for height does not depend on whether height was measured in inches or in centimeters. Likewise, CORRELATION is calculated from standard scores so that, for example, one could compare the correlation between years of education and income across cultures without concern for different monetary units in different countries. The standardization implied by the term *standard score* has many practical advantages.

—Irwin P. Levin

STANDARDIZED REGRESSION COEFFICIENTS

In ORDINARY LEAST SQUARES (OLS) MULTIPLE REGRESSION analysis, an *UNSTANDARDIZED* regression coefficient, b , describes the relationship between a DEPENDENT and an INDEPENDENT VARIABLE in terms of the original *units* of measurement (dollars, kilograms, scale scores, years) of those variables. A one-unit change in the independent variable is expected to produce b units of change in the dependent variable. For example, a 1-year increase in the number of years of school completed may result in a $b = \$1,024$ increase in annual income. A *standardized* coefficient, b^* , expresses the same relationship in STANDARD DEVIATION units: A one-standard-deviation increase in the number of years of school completed may result in a $b^* = .275$ standard deviation increase in annual income. In OLS regression, the standardized coefficient b^* can be calculated in either of two ways. One is to TRANSFORM all variables to Z-SCORES or STANDARDIZED VARIABLES (from each variable, subtract its mean, then divide the result by its standard deviation) prior to the REGRESSION analysis. The other is to multiply the unstandardized coefficient for each independent variable by the standard deviation of that independent variable, then divide by the standard deviation of the dependent variable: $b^* = (b)(s_x)/(s_y)$, where y is the dependent variable, x is the independent variable, s_y is the standard deviation of y , s_x is the standard deviation of x , and b and b^* are the unstandardized and standardized coefficients, respectively, for the relationship between x and y .

Standardized coefficients are used for two main purposes. First, when independent variables are measured in different units (for example, years of schooling for one variable, IQ score for another, etc.), it is difficult, based only on the unstandardized coefficients, to discern which of two or more independent variables has more impact on the dependent variable. The same variable measured in different units (centimeters, meters, or kilometers) will have a larger or smaller unstandardized regression coefficient. Using standardized coefficients converts all of the coefficients to a common unit of measurement (standard deviations), and the standardized coefficient is the same regardless of the units in which the variable was originally measured. A larger standardized coefficient for one independent variable as opposed to a second

independent variable allows us to conclude that the first independent variable has a stronger influence than the second independent variable, even when the two independent variables were originally measured in very different units. Second, standardized coefficients are used in PATH ANALYSIS to calculate indirect and total effects, as well as direct effects, of an independent variable on a dependent variable. In a *fully RECURSIVE* path model, it is possible to “decompose” the correlation between an independent variable and a dependent variable into the direct influence and the indirect influence (the independent variable influences other variables, which in turn influence the dependent variable) of the independent variable. In the special case of a single independent variable, the standardized regression coefficient is equal to the correlation between the two variables.

Moving beyond OLS multiple regression, Goodman (1973a, 1973b) constructed what he called a “standardized” coefficient for LOGIT MODELS by dividing the unstandardized coefficient by its standard error, but this is really just a variant of the Wald statistic sometimes used to test the STATISTICAL SIGNIFICANCE of LOGISTIC REGRESSION coefficients. Goodman also attempted to construct a parallel to path analysis using the logit model, but the path analysis analogue he proposed did not permit the calculation of indirect effects or the decomposition of CORRELATIONS between dependent and independent variables (Fienberg, 1980). More recently, Menard (1995) reviewed other attempts to construct standardized logistic regression coefficients and suggested a procedure for a *fully standardized logistic regression coefficient*, standardized on both the dependent and the independent variables, as opposed to partially standardized logistic regression coefficients, which are standardized only on the independent variable. Menard (1995) and work in progress by Menard (in press) suggests that this fully standardized logistic regression coefficient can be interpreted in much the same way as the standardized OLS regression coefficient, and that it can be used in path analysis with logistic regression, including calculation of indirect effects and decomposition of correlations between dependent and independent variables.

STANDARDIZED TEST

Standardized tests are used to measure cognitive skills, abilities, aptitudes, and achievements in a variety of applications in psychology, education, and other social sciences. Standardized MEASURES also have been developed to assess personality, attitudes, and other noncognitive characteristics. However, the focus of the present entry is on the measurement of cognitive characteristics, which are often referred to as tests.

A standardized test is a measure of a well-articulated CONSTRUCT, has clearly stated purposes, is developed using highly structured procedures, is administered under carefully controlled conditions, has a systematic basis for score interpretation, and is shown to possess various technical properties.

CONSTRUCT DEFINITION

Standardized tests are measures of constructs. The AERA/APA/NCME (1999) *Test Standards* define a construct “broadly as the concept or characteristic that a test is designed to measure” (p. 5). In aptitude testing, a test might be constructed to measure the construct spatial ability. In achievement testing, a test might be developed to measure the construct mathematics achievement. A major component of standardized tests is the construct definition, which is a clear statement of the construct that is to be measured by the test. A construct definition provides a foundation for developing a test to measure that construct and for validating the test.

TEST DEVELOPMENT

Systematic procedures are used to develop standardized tests. Test development procedures help provide an OPERATIONAL definition of how a test assesses

the construct. For standardized aptitude tests, the different item types included on the test are specified, as are the rules for developing items. For standardized achievement tests, detailed tables of specifications are developed that indicate the item types, content areas, and cognitive skill levels of the items to be included. Such test specifications provide test developers with a blueprint for test construction.

Standardized tests also have detailed statistical specifications. Pretest procedures are used to understand how test items function for examinees before the test items are included on the operational versions of the tests. Statistical indexes of item difficulty and discrimination are often calculated based on pretesting. Statistical specifications indicate how many items of various levels of difficulty and discrimination are included on the test.

The use of detailed content and statistical specifications is a requisite condition for the development of alternate forms of test, which are different sets of test items that can be expected to produce scores with very similar meanings and statistical properties. Alternate forms enhance test security and allow tests to be administered to an examinee more than one time.

TEST ADMINISTRATION

Standardized tests have strictly controlled administration conditions: Examinees are given explicit instructions, test booklets or other testing materials are provided in the same manner to all examinees, time allowed for testing is carefully controlled, the same answer documents or procedures are used for all examinees, and the use of other tools such as calculators and scratch paper is controlled and specified.

EXAMINEE RESPONSES

Many standardized tests use a multiple-choice format that requires examinees to indicate which one from a set of possible answers is the correct one. Other objectively scored item formats also exist, such as true-false. On some tests, examinees might be asked to provide short answers to questions or extended answers, such as with an essay test, and on other tests, examinee behavior is observed.

SCORING PROCEDURES

Well-defined scoring procedures are used with standardized tests. For objectively scored tests, a raw

score often is defined as the number of items that the examinee correctly answered. Other, more complex raw scores, such as partial credit scores, are sometimes used. For tests in which examinees provide short or extended answers, human judges are used to score the responses. In such cases, detailed scoring rubrics are used that provide explicit guidelines to the judges on how to score the responses.

SCORE SCALES

Raw scores on standardized tests are TRANSFORMED to SCALE scores to facilitate score interpretation. Score scales can be normatively based. For example, norming studies are conducted for intelligence tests in which the test is administered to a group of examinees that is intended to represent a particular population, such as, for example, 14-year-olds in the United States. The mean raw score from the norming study might be set equal to a scale score of 100. Other normative points are used to set other points on the score scale.

Proficiency-level scoring sometimes is used with educational achievement tests. In proficiency-level scoring, a standard setting study is conducted in which, through a systematic procedure, judges define the raw score an examinee needs to be at or above for a particular proficiency level. Often, a series of proficiency levels is defined in this process. One set of frequently used proficiency levels is *basic*, *proficient*, and *advanced*.

Norms and proficiency levels provide test users a foundation for interpreting scores. As such, they are a major component of standardized tests.

TEST SECURITY

It is important that the scores on the test represent the construct that is being measured. However, if the test questions become known to future examinees, performance might not reflect the examinees' proficiency on that construct. For this reason, many standardized testing programs have elaborate test security procedures. The procedures include using alternate forms, keeping tight control over testing materials, and sometimes running statistical analyses after test administrations to identify irregularities in security.

RELIABILITY

Standardized tests are developed to produce scores that have sufficient RELIABILITY for making important

decisions. Decisions about testing time, numbers of test questions, and types of questions to include on the test are made to ensure that the scores have sufficient reliability for their intended purposes.

VALIDITY

Test VALIDITY is the degree to which evidence supports interpretations of test scores. A test validation process involves collecting evidence that provides a sound scientific basis for score interpretations. Validation begins with statements of the construct to be measured, the purposes of the test, and the interpretations to be made of the scores. Various types of evidence are collected to support the validity of the test. Sources of validity evidence can be based on test content, examinee response processes, and a study of the internal psychometric structure of the test, as well as by relating the test scores to other variables. Evidence that the test is not influenced by variables extraneous to the construct being measured is an important component of a validation process. A sound validity process integrates the different sources of evidence to support the intended interpretation of test scores for specific uses.

SPECIAL ISSUES

In recent years, the administration of some standardized tests has moved to computers, creating new challenges for the development of standardized tests. PSYCHOMETRIC test theories, such as ITEM RESPONSE THEORY and GENERALIZABILITY THEORY, have seen major advances in recent years, leading to better understanding of the technical properties of standardized tests and making possible new procedures for administering and scoring standardized tests.

STANDPOINT EPISTEMOLOGY

Standpoint epistemology developed from feminist criticisms regarding women's absence from, or marginalized position in, social science. Although social science was supposedly OBJECTIVE and value free, feminists argued that it was conducted largely from male perspectives and male interests. In order to make the meaning of women's lives more visible, it was necessary to analyze it from their point of view. The significance of standpoint epistemology lies in its challenge to descriptions and classifications of social life that are based on universalistic male assumptions. Key is the idea that women and men lead lives with differing contours, creating different kinds of knowledge. Women's experience of oppression produces particular and privileged understandings. This access to different knowledge is able to reveal the existence of forms of human relationships that may not be visible from the position of the ruling male gender. Therefore, standpoint epistemology offers the possibility of new and more reliable insights into gendered power and relationships. It has significance for the practice of FEMINIST RESEARCH, for example, through emphasizing the importance of listening to women's voices. It also has possibilities for extension into understanding the lives of other (e.g., minority, ethnic, and disabled) groups.

Variations exist in how a feminist standpoint might be conceived and its implications for knowledge, with some using the expression *theory*, rather than *epistemology*, because of the latter's association with certainty and neutrality. It is also suggested that standpoint is a practical achievement, rather than an ascribed status; subordination alone does not lead to an awareness of inequality and oppression. One major difficulty with a standpoint approach is that it risks replacing a generalized male perspective with that of a generalized woman. Recently, feminists have questioned the idea that the nature of womanhood is fundamental or intrinsic, and that women's oppression is universal, homogeneous, and shared. They have moved to an emphasis on difference and diversity among women,

particularly focusing on the structural positions derived from ethnicity, sexuality, disability, class, and age. This has led to a proliferation of differing standpoints, for example, those of some Black and lesbian feminists. Yet such an approach also raises problems about the existence of a multiplicity of incommensurable standpoints and of RELATIVISM. It assumes that one structural position alone, rather than multiple positions—which may invoke conflict or tensions—provides particular knowledge. There is also the risk that orthodoxies develop around particular standpoints and ways of being and seeing, so that some women might be judged as deviant from an assumed norm.

The usefulness and implications of standpoint epistemology have been extensively debated, and disagreements abound. However, there is some consensus that it highlights the relationship between women's experiences and feminist knowledge and between knowledge and power. There is no such thing as a disinterested knowledge, and adopting a standpoint draws attention to the subject at the center of knowledge production.

STATA

Stata is a general-purpose statistical software package that has gained popularity in recent years in the social sciences, at least in part because of its flexibility in implementing many user-written, nonetheless well-maintained, macros. For further information, see the Web site of the software: <http://www.stata.com>.

—Tim Futing Liao

STATISTIC

A *statistic* is simply a numerical summary of the SAMPLE DATA. For example, data analysts often

use familiar sample statistics such as sample MEANS, sample VARIANCES and STANDARD DEVIATION, sample PERCENTILES and MEDIANS, and so on to summarize the samples of QUANTITATIVE data. For samples of CATEGORICAL data, sample proportions, percentages, and ratios are typical sample statistics that can be utilized to summarize the data. In short, a statistic is simply a summary quantity that is calculated from a sample of data.

The counterpart of a statistic for the entire POPULATION is called a *parameter*. A statistic differs from a PARAMETER in at least two aspects. First, a statistic describes or summarizes a characteristic of the sample, but a parameter refers to a numerical summary of the population from which that sample was drawn. Note that values of sample statistics depend on the sample selected. Because their values vary from sample to sample, sample statistics are sometimes called RANDOM VARIABLES to reflect that their values vary according to the sample selected.

Second, the value of a parameter is usually unknown or not feasible to obtain, but the quantity of a statistic can be directly computed from the sample data. The primary focus of most social research is the parameter of the population, not the sample statistic calculated from selected observations. Thus, if the population of one's research interest is small and data exist for an entire population, then one would normally explore the population parameter rather than the sample statistic. However, in most social studies, researchers still use sample statistics to make inferences on the values of population parameters because (a) populations for social research are usually very large, so it is impractical to collect data for the entire population; and (b) one can still have good precision in making inferences about (or guessing) the true values of population parameters *if* appropriate sampling techniques and statistical methods are utilized. For example, samples taken by professional polling and research institutions, such as the Gallup, the General Social Survey, and the National Election Study, typically contain about 1,000 to 2,000 subjects.

One important issue for using a sample statistic to PREDICT or infer a parameter value is how accurate the prediction is. In other words, it is useful for data analysts to know the likely accuracy for predicting the value of a parameter by using a sample statistic. A conventional way to account for the uncertainty of predictions is to report the CONFIDENCE INTERVALS of POINT ESTIMATES of parameters. We usually use analogous sample statistics as the point estimates

(e.g., sample mean and population mean, sample variance and population variance). In addition, researchers may also set a “desired precision” of prediction before data collection. This desired precision (also defined as error bounds) in turn can help researchers decide the required sample size for obtaining reliable sample statistics. More information on confidence intervals of sample statistics and the relationship between sample size and accuracy of estimation using sample statistics may be found in William L. Hays (1994), Alan Agresti and Barbara Finlay (1997), and Richard A. Johnson and Gouri K. Bhattacharyya (2001).

STATISTICAL COMPARISON

Most social scientists would agree that one of the *raison d'être* for the social sciences is comparison, which provides insight that we would not gain otherwise. The tradition of comparison goes back to the beginning of the social sciences and is evidenced in the works of Emile Durkheim and Max Weber. Today's social research of a comparative nature ranges from the COMPARATIVE RESEARCH of societies and nation-states, whether or not large national samples are used, to small-*N* case studies using the COMPARATIVE METHOD. As long as comparative researchers use a certain form of numerical data, they will typically make some kind of *statistical comparison*. A search on the Internet of “statistical comparison” would result in hundreds of hits that contain the term, some of which are social science studies. But what type of statistical comparison did the studies do? Whereas some are simply a listed comparison of two sets of figures, such as rates and AVERAGES, from two aggregates of people, others may involve some form of SIGNIFICANCE TESTING, with the aim to provide an INFERENCE about the POPULATION from SAMPLE statistics. The purpose of this entry is to give an overview of the wide range of possible statistical comparisons.

COMPARISONS OF MEANS

Often, researchers are interested to see if one group of people on average has certain attributes at a higher level than another group of people. This is a comparison of two MEANS. For example, one may be interested in comparing the mean incomes [$E(Y_a)$ and $E(Y_b)$] of the two groups of people *a* and *b*. The NULL HYPOTHESIS states that $E(Y_a) = E(Y_b)$, and typically, the *t*-TEST is applied when sample data are analyzed. A comparison like this lies at the heart of an EXPERIMENT. For further discussions along these lines, see Anderson et al. (1980).

Although the selection of subjects into the TREATMENT and CONTROL GROUPS is randomized in an experiment, in most social science research, the group variable in comparison is fixed (such as sex, race, and nation of origin), regardless of whether the individuals are drawn from one sample or separate samples.

The idea of comparing two means can be extended to making MULTIPLE COMPARISONS. The methodology for comparing multiple means includes many alternatives, such as the BONFERRONI TECHNIQUE, the SCHEFFÉ TEST, and Tukey's method. A major purpose of the one-factor ANALYSIS OF VARIANCE is also to assess potentially different response means from multiple groups.

COMPARISONS OF VARIANCES

If one is interested in assessing the difference in variance of two distributions, such as income, then one is concerned about the equality of the two variances; or, alternatively, the null hypothesis is $var(Y_a) = var(Y_b)$. The *F* TEST can be applied to the assessment of variance equality. This will be a useful test, especially when the two mean incomes may be identical but one income distribution may represent a perfect middle-class society where everyone has an income level located around the mean, whereas the other distribution comes from a society with much inequality where earning powers differ a great deal. For the analysis of variance inequality among multiple groups, LEVENE'S TEST is appropriate.

COMPARISONS OF DISTRIBUTIONS

Although variances are a property of DISTRIBUTIONS, there are more formal ways of comparing distributions, which can be studied in terms of their *proportionate* distribution, their *relative* distribution, and their *theoretical* distribution. All of these are

concerned about the shape and the general differences between two (or more) distributions as opposed to the differences in value between two (or more) parameters, such as the mean and the variance.

The method employing the Lorenz curve and the GINI COEFFICIENT showcases the first approach, where the researcher asks the question about the cumulative proportion of Y (or income) that is held by the cumulative population share. This method is popular for studying income inequality, and two (or more) overlaying Lorenz curves can directly compare two (or more) distributions with associated Gini coefficients to assist the comparison.

The RELATIVE DISTRIBUTION METHOD is concerned with full distribution comparison based on the so-called relative distribution. Simply defined, the relative distribution is a distribution resulting from computations involving the two distributions under investigation. Either the cumulative distribution function or the PROBABILITY DENSITY FUNCTION (PDF) of the relative distribution can be studied. For example, the PDF of the relative distribution of two income distributions is uniform.

Distributions can also be compared against a theoretical model. For example, researchers may be interested in whether both distributions follow the NORMAL DISTRIBUTION. It is possible that the distribution from one sample follows the normal and the distribution from another sample follows the log-normal. Such comparison may as well assist in identifying possible ASSUMPTION violations of a statistical method like the GENERAL LINEAR MODEL.

COMPARISONS OF RATES

Sometimes, researchers are interested in comparing rates of event occurrence instead of mean values of a variable. For example, a study may compare the unemployment rates of two populations. Because of the effect of potential CONFOUNDING factors, the two rates may not be directly comparable without some kind of ADJUSTMENT. A method of choice in this case is RATE STANDARDIZATION, which standardizes the rates in comparison with a standard population composition (i.e., ridding the rates of the confounding effect).

COMPARISONS OF REGRESSION PARAMETERS

When conducting a MULTIPLE REGRESSION ANALYSIS to study the impact of certain INDEPENDENT VARIABLES

on the DEPENDENT VARIABLE, researchers often are interested in comparing these parameters across samples or groups. For example, in studying income, one may be interested in comparing the effect of age (β_1) and of educational attainment (β_2) between men (m) and women (f). There are three possible null hypotheses:

1. $H_0 : \beta_{1m} = \beta_{1f}$
2. $H_0 : \beta_{2m} = \beta_{2f}$
3. $H_0 : \beta_{1m} = \beta_{1f} \text{ and } \beta_{2m} = \beta_{2f}$

There are several ways of testing Hypotheses 1 and 2. A popular way is to run a regression analysis on the combined sample with two interaction terms, one being the interaction between age and the sex DUMMY VARIABLE, and the other being the interaction between educational attainment and the sex dummy. A t -test of either of the interactions assesses either Hypothesis 1 or 2. Hypothesis 3 may also be assessed in different ways. One way is to run two regression models, one with the two interaction terms and the other without them; then, an F test of the R -SQUARED incremental is conducted. A variation of Hypothesis 3 tests not just the equality of the parameters for age and education but also that for the sex dummy variable. The method of assessment is the CHOW TEST, which evaluates whether the two sex groups differ at all in their income levels.

COMPARISONS IN THE GENERALIZED LINEAR MODEL

The hypotheses discussed above can be easily extended to other regression-type models, such as the LOGIT, the PROBIT, the MULTINOMIAL LOGIT, and the POISSON REGRESSION models, which are all members of the GENERALIZED LINEAR MODEL. Although the hypotheses can be formed similarly, the testing will be different. Interested readers are referred to Liao (2002).

COMPARISONS IN OTHER STATISTICAL MODELS

Similarly, comparisons can be made in more advanced methods such as LATENT CLASS ANALYSIS, STRUCTURAL EQUATION MODELING, and MULTILEVEL ANALYSIS. One's earning power can perhaps be better studied as a LATENT VARIABLE. Because individuals belonging in the same higher-level unit are more alike, they behave as DEPENDENT OBSERVATIONS, and the multilevel nature of the social structure can and should

be taken into account. Statistical comparison in these methods, as well as the methods covered so far, is discussed in greater detail in Liao (2002).

STATISTICAL CONTROL

Statistical control refers to the technique of separating out the effect of one particular INDEPENDENT VARIABLE from the effects of the remaining variables on the DEPENDENT VARIABLE in a MULTIVARIATE ANALYSIS. This technique is of utmost importance for making valid INFERENCES in a statistical analysis because one has to hold other variables constant in order to establish that a specific effect is due to one particular independent variable. In the statistical literature, phrases such as “holding constant,” “controlling for,” “accounting for,” or “correcting for the influence of” are often used interchangeably to refer to the technique of statistical control. Statistical control helps us to better understand the effects of an independent variable, say, X_1 , on the dependent variable Y because the influence of possibly CONFOUNDING or SUPPRESSING variables X_j ($j > 1$) is separated out by holding them constant.

How is this technically done when we estimate a particular MODEL? Suppose we find that campaign spending (X_1) increases turnout (Y) at the electoral district level. In order to establish the campaign spending effect, we want to know whether this relationship is confounded, suppressed, or SPURIOUS if we include control variables in our model that account for alternative explanations. The expected closeness of a district race (X_2) is such an alternative explanation. We expect that close races should particularly motivate voters to turn out on Election Day. Consider the following LINEAR regression model,

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \varepsilon.$$

The specific effect β_1 of campaign spending on turnout in the classical REGRESSION framework is estimated as

$$\hat{\beta}_1 = \frac{\sum (X_1 - \hat{X}_1)(Y - \hat{Y})}{\sum (X_1 - \hat{X}_1)^2},$$

where $\hat{X}_1 = \alpha_0 + \alpha_1 X_2$ is predicted from a regression of X_1 on X_2 ; and $\hat{Y} = \gamma_1 + \gamma_2 X_2$ is predicted from a regression of Y on X_2 . Thus, the estimated campaign spending effect $\hat{\beta}_1$ solely depends on variation in X_1 and Y , because any linear impact of X_2 in the terms $X_1 - \hat{X}_1$ and $Y - \hat{Y}$ is subtracted. Consequently, $\hat{\beta}_1$ is calculated based on terms that are independent of X_2 . When estimating the specific effect of X_1 on Y , we hold constant any possible distortion due to X_2 because the relationship between X_1 and Y no longer depends on X_2 . Thus, statistical control separates out the specific effect $\hat{\beta}_1$ of X_1 on Y corrected for any influence of X_2 . At the same time, statistical control also disentangles the specific effect $\hat{\beta}_2$ of X_2 on Y corrected for any influence of X_1 . Thus, this technique does not treat our key explanatory variable any different from other (control) variables. The logic behind statistical control can be extended to more independent variables even for GENERALIZED LINEAR MODELS.

Statistical control comes with simplifying ASSUMPTIONS, though. Ideally, one likes to implicitly hold confounding factors constant, such as in experimental control through randomization. Because this is often not possible with observational data, one has to explicitly identify factors before one can statistically control for them. Furthermore, statistical control assumes that possible confounding effects are linear and additive, that is, they are independent of the particular level of any other variable in the model. Coming back to the running example, the expected closeness of the race is assumed to have the same impact on campaign spending and turnout no matter how close the race is expected to be. If these assumptions prove to be wrong, one can include product terms of the variables in the model to control for possible conditional or INTERACTION EFFECTS or restrict estimation of the model to subpopulations in which the assumptions hold.

STATISTICAL INFERENCE

Statistical inference is the process of making PROBABILITY statements about POPULATION PARAMETERS when we have only SAMPLE statistics. Population parameters are fixed quantities that are rarely known with certainty. If we know the population, then we can calculate (rather than estimate) population parameters. However, we usually do not know the population, so we must estimate population parameters from a sample. Such PARAMETER ESTIMATES always have some associated uncertainty because they are subject to SAMPLING ERROR. Therefore, we make statistical inferences about their likelihood of reflecting the true population parameter.

Understanding statistical inference requires understanding the concept of a SAMPLING DISTRIBUTION. A sampling distribution is a probability distribution of outcomes on a sample statistic when drawing all possible random samples of size N from a population. Often, a sampling distribution is represented as a two-dimensional graph, with each possible value of the sample statistic arrayed on the horizontal axis and the probability of each possible value of the sample statistic arrayed on the vertical axis. In reality, social science researchers typically draw only a single sample from the sampling distribution. However, knowledge of the sampling distribution enables us to make probability statements about sample statistics relative to the true population parameter.

We rely on fundamental theorems of statistics to make probability statements about whether a sample statistic is reflective of the true population parameter. For example, a fairly weak tool of statistical inference is Chebychev's theorem, which states that the probability of an estimate lying more than k standard deviations away from the mean of its distribution is $\frac{1}{k^2}$. For example, suppose we sample randomly from a distribution of any shape and obtain a POINT ESTIMATE of a population parameter. Then, Chebychev's theorem would state that the probability that the point estimate is more than 2 STANDARD DEVIATIONS away from the true mean of the SAMPLING DISTRIBUTION of estimated parameters is only $\frac{1}{4}$.

A more useful set of theorems enabling statistical inference is the family of central limit theorems. The Lindberg-Levy variant of the CENTRAL LIMIT THEOREM states that if repeated samples of size N are drawn from a probability distribution of any shape with mean μ and variance σ^2 , then as N grows large, the sampling distribution of sample means approaches normality with mean equal to the population mean μ and variance equal to $\frac{\sigma^2}{N}$. This result is important because it implies that regardless of the distribution of the population from which a sample statistic is drawn, the sampling distribution of sample statistics will be normally distributed with mean equal to the true population parameter and variance computable from the population variance and N . With this information, probability statements can be made based on the sample statistic and its variance.

A wide variety of other distributions can be used in statistical inference depending on the nature of the statistic to be inferred and the assumptions the analyst is willing to make. For example, it may be unrealistic to treat the population variance as known. In this case, the t -distribution is often used. Other distributions that are commonly used are the CHI-SQUARED and F distributions. The chi-squared distribution is commonly used in situations involving the sums of squares of normally distributed variables. The F distribution is often used for evaluating the ratio of independent chi-square variables.

STATISTICAL INTERACTION

For mathematical statisticians, statistical interaction refers to those situations in MULTIVARIATE ANALYSES where the relationships among variables differ

depending on different values of the variables. In the simplest three-variable case, the relationship between two variables *A* and *B* is different depending on the values of a third variable *C*. If there is no interaction, relationships among variables are *additive*—that is, for the case of a single DEPENDENT VARIABLE, we can sum the effects of INDEPENDENT VARIABLES to determine the overall effect of all the independent variables on the dependent variable, and this sum will be constant, regardless of the values of the different independent variables. Statistical relationships can be NONADDITIVE, as represented by interaction effects. Physicists refer to this as *superposition*. If there is interaction, then superposition breaks down. Such failure of superposition is a characteristic of NONLINEAR systems.

There are a variety of statistical procedures that can detect interaction. ANALYSIS OF VARIANCE (ANOVA) techniques typically allow for the specification of models that include interaction terms, and there are exploratory analogues to ANOVA techniques. There are two variants on reporting interaction. One is to write an interaction term into a linear equation. The other is to report a model of determination that specifies that interaction is significant. Sometimes, we can specify a social process that engenders the interaction. For example, in a study of the relationship between housing and health conditions, it was found that for all age groups under 65, there was a positive relationship between quality of housing and quality of health. For those over 65, the relationship was negative. The causal process was that poor health was a determinant of the allocation of elderly households to very high-quality sheltered accommodation. In general, housing conditions had a causal influence on health. For the elderly, health had a causal influence on housing conditions (Byrne, McCarthy, Harrison, & Keithley, 1986). However, such straightforward explanations are not always possible.

Marsh (1982) noted that “interaction is a headache from a technical point of view but most exciting from the standpoint of substantive sociology” (p. 91). From a REALIST perspective, the existence of interaction is a challenge to the whole analytical program that informs traditional statistical reasoning. If we use a language of VARIABLES, at the very least the existence of interaction demonstrates that causal processes are local/contextual rather than universal. In other words, it is impossible to specify general laws because “circumstance [values of interacting variables] alter

cases.” Another way of putting this is to say that we are dealing with complex and contingent generative mechanisms. However, interaction might also indicate the presence of *emergence*—the scientific term that summarizes the expression “the whole is greater than the sum of its parts.” If we are dealing with *complex systems* with emergent properties, then there is an argument to the effect that VARIABLES are reifications rather than realities, and we should address the properties of whole systems rather than of artificial and unreal abstractions from them. At the very least, the existence of interaction alerts us to the possibility of complex relationships, and we might argue that the detection of interaction in a multivariate analysis invalidates any “linear” approach to reasoning about cause in the system(s) being investigated.

STATISTICAL PACKAGE

Statistical packages are collections of software designed to aid in statistical analysis and data exploration. The vast majority of quantitative and statistical analysis relies upon statistical packages for its execution. An understanding of statistical packages is essential to correct and efficient application of many quantitative and statistical methods.

Although researchers can, and sometimes do, implement statistical analyses in generalized programming languages such as FORTRAN, C++, and Java, statistical packages offer a number of potential advantages over such “hand coding.” First, statistical packages save the researcher time and effort: Statistical packages provide software for a range of analyses that would take years for an individual programmer to reimplement. Second, statistical packages can provide a unified operating framework and common interface for data manipulation, visualization, and statistical analysis. At their best, tools within a package can easily be combined and extended, enabling the

researcher to build upon previous work. Furthermore, even where a statistical procedure is simple enough or specialized enough to be programmed by hand, statistical packages offer user interfaces that make it far easier for others to use new procedures. Third, statistical packages are more likely to produce correct results than are hand-coded routines. Even simple tasks, such as computing the standard deviation, can be tricky to implement in a way that yields reliably accurate results. Statistical packages are likely to be tested more extensively for bugs and numerical problems, and the implementations of these packages are usually more familiar with modern numerical methods than is the typical researcher. Fourth, statistical packages are likely to be faster than average implementations: A considerable amount of effort and refinement goes into the choice of algorithm for a particular analysis or statistical tool, and also into tuning the software to work well on a specific computer architecture.

The chief problems researchers face when using statistical packages are choosing a package from the hundreds now available, and ensuring that the results obtained from it are correct and replicable. Obviously, each package will differ in terms of the features that it supports, although there is considerable overlap among many large packages. Commercial giants such as SAS[®] and SPSS[®], and large open-source packages such as “R,” offer thousands of data manipulation, visualization, and statistical features. The interfaces of the packages vary considerably as well: from the point-and-click style of SPSS to the command-line-based approach of SAS and R. Unless a particular package offers a crucial feature, the researcher may want to consider a modern statistical language such as “S,” which has broad functionality and both commercial (“S+”) and open-source implementations (“R”) (see Venables & Ripley, 2002, for an introduction).

Less obviously, packages differ significantly in terms of speed, accuracy, and extensibility. When approaching a statistical package, researchers may want to ask: Has this package been tested for accuracy? Does it document the algorithms it uses to compute statistical analyses and other quantities of interest? Was it designed to efficiently process data of the size and structure to be used in the proposed research project? What programming facilities are available? Does the programming language support good programming practices, such as object-oriented design?

Are the internal procedures of the package available for inspection and extension? How easy is it to use this package with an external library, or as part of a larger programming and data analysis environment?

Although statistical packages are viewed as essential tools for constructing an analysis, they are often considered highly interchangeable. Thus, once results are obtained, researchers often fail to document the package used in subsequent publications. In fact, however, statistical packages vary greatly with respect to accuracy and reliability, and reported results may be dependent on the specific package and version, and the computational options used during the analysis (McCullough & Vinod, 1997).

There are several approaches to ensuring accurate results. One may want to replicate the results across different packages while using different algorithms, to check that different methods of computing the results yield the same answer. In packages that support extended precision, increasing the numerical precision of computations during the analysis can be useful in avoiding certain types of numerical error. Another approach is sensitivity analysis, where small amounts of noise are introduced into calculations, data, and/or starting values in order to verify that the solution found is numerically robust (Altman, Gill, & McDonald, 2003).

Finally, three steps should be taken to increase the replicability of the results. Because complex analysis may depend on the particular computational strategy used both in researchers’ analysis and within the statistical package, reporting (or archiving) the code used to run the analysis, the package and version used, and any computational options used during the runs is essential to ensuring replicable results. Archiving a copy of the statistical package itself may be warranted in some cases where exact replication is vital; although a few packages have the ability to replicate the syntax rules and computational options used in older versions, most packages change both the programming syntax and implementation over time. Second, many social science data sets are difficult or impossible to re-create—publicly archiving any unique data used for an analysis is often a necessity for successful replications. Third, the formats that statistical packages use are often both proprietary and subject to change over time, posing grave obstacles to later use. Researchers can ensure that the data remain accessible even as proprietary formats change by exporting data using a plain-text format, along with adequate documentation

of missing values, weights, and other special coding of the data (Altman et al., 2003).

STATISTICAL POWER

In using SAMPLE DATA to test HYPOTHESES about POPULATION values, one possibility is that the data will lead you to retain the NULL HYPOTHESIS even though it is false. This is TYPE II error (β). To accentuate the positive rather than the negative, however, the term *power* has been used to define the converse of Type II error: The power of a statistical test is the probability of correctly rejecting the null hypothesis when it is false, or $P = 1 - \beta$. Statistical power is an extremely important concept because most social science research is designed to demonstrate that a particular variable does, in fact, influence behavior. We set out to find evidence that the “hypothesis of no effect” (the null hypothesis) is indeed false. We want to demonstrate that a particular form of therapy is effective, that an educational program works, that world events do influence political opinion, and so forth. To do these things, we desire high levels of statistical power.

Although statistical power will decrease when α , the probability of a TYPE I ERROR (rejecting a true null hypothesis), is set low, there are some principles of good EXPERIMENTAL DESIGN that can be used to increase power: use large samples, develop reliable response measures, select homogeneous subject populations, use repeated measures on the same subjects, and use STANDARDIZED and unambiguous tasks and instructions. One factor that we cannot control, however, is the true value of the POPULATION PARAMETER being estimated by our statistical test. The greater the discrepancy between the value stated in the

null hypothesis and the true situation, the greater the statistical power. Logically (and fortunately), we will be more apt to detect the effect of a strong (*powerful*) treatment than a weak one. Some researchers plot power functions or power curves to show how the power of their statistical test varies depending on the degree of falsity of the null hypothesis (Cohen, 1988). Conversely, some researchers will consult previous studies or conduct their own PILOT work to estimate the size of their experimental effect and then use this to determine the sample size they would need in their main study to attain a predetermined level of statistical power, say .90. (See Cohen, 1988, for how this is done.)

Hays (1994) likens statistical power to the power of a microscope. Just as a high-powered microscope increases our chances of detecting something not readily visible with a low-powered instrument, so does a high-powered test increase our chances of detecting when the null hypothesis is false. However, even a high-powered microscope is limited by the size of the object it is attempting to detect. So it is that, all other things being equal, the larger the effect that we are trying to detect in our research, the greater will be the power of our tests for detecting it. Good research techniques will also increase the likelihood of detecting the effect.

STATISTICAL SIGNIFICANCE

When an ESTIMATE achieves statistical significance, the thing estimated is likely to be not zero, and so becomes especially worthy of further attention. Significance tests are applied to UNIVARIATE statistics, such as the mean; to BIVARIATE statistics, such as PEARSON'S CORRELATION COEFFICIENT; and to multivariate statistics, such as the slope coefficient in a MULTIPLE REGRESSION equation. For example, if a Pearson's correlation coefficient between variable *X* and variable *Y* attains statistical significance at .05, the level most commonly used, then we can reject the

NULL HYPOTHESIS that X and Y are not related in the population under study. If, however, the correlation is not found significant at .05, we tend to think, at least initially, that the link between X and Y does not merit further study. Thus, statistical significance serves as a gatekeeper, encouraging further consideration of coefficients that “pass through the gate” and discouraging further consideration of coefficients that fail to “pass through the gate.”

STEM-AND-LEAF DISPLAY

Developed by John Tukey, a stem-and-leaf plot is a way of visually representing a DISTRIBUTION of data values. The stem represents a major unit for grouping the values, and the leaf represents a subdivision of that unit. Each possible stem value is marked even when no cases belong to that group. It then becomes possible to observe where values bunch, gaps in the distribution, and whether the distribution appears to be SKEWED. The stem-and-leaf plot can also indicate outlying values. In order to best represent the distribution of the data, the unit for the stem has to be selected so as not to condense the data too much, but also so as not to provide so much detail that the pattern of the data becomes indistinguishable. Stem values can be divided or multiplied by 2, 5, or 10 to expand or condense the summary of the distribution provided. For example, Table 1 shows a set of 30 household income values from a British survey of the late 1990s.

If the stem values are set in units of 10, the ensuing stem-and-leaf values from the original data values are those shown in the second column of the table, and they are represented on the stem-and-leaf plot as illustrated in Figure 1.

Here, in what can be described as a form of horizontal HISTOGRAM, we can see that the distribution peaks in the £130–£139 range, although it also has a smaller, earlier peak at incomes around £80. We can see that there are gaps in the 110s, the 160s, and the 190s. These could represent breaks in the distribution that indicate separate distributions, although they could also stem from the small size of the sample. There are no values above £200 up to the value of £274, so rather than represent the empty stem points and thus

Table 1 Sample of 30 Cases From a British Income Distribution and Values as Marked on Stem-and-Leaf Plots

creating a longer and more straggling stem, the top value of £274 has simply been indicated at the end as an OUTLIER.

In this stem-and-leaf plot, the exact values of the original data have been retained: We know that the lowest value is £61 and the third highest is £188. If the stem is reduced from divisions of 10, the values may be simplified. For example, if each point on the stem represents a range of £20, then the leaf can simply distinguish points according to which of the two £10 ranges they fall into. In Figure 2, the values from

Figure 1 Stem-and-Leaf Plot of Data in Table 1

NOTE: Stem unit is £10; leaf unit is £1.

Figure 2 Stem-and-Leaf Plot of Data in Table 1

NOTE: Stem unit is £20; leaf unit covers the range £x0–£x9.

the third column of Table 1 have been illustrated on a stem-and-leaf plot. Here, the number of the stem point gives the number of hundreds, with the following symbol indicating which £20 division is referred to: The “*” represents the range from 0 to 19, “t” the twenties and thirties, “f” the forties and fifties, “s” the sixties and seventies, and “.” the eighties and nineties. The leaf number simply indicates which of the two possibilities is actually contained within the data.

Here, the shape of the distribution with two clear peaks and a trailing end is emphasized, although at the loss of more detailed definition. In this example, if the scale is reduced even further, such as into £50 stem

STEP FUNCTION. See INTERVENTION ANALYSIS

STEPWISE REGRESSION

Given a set of potential EXPLANATORY VARIABLES that could be included in a LINEAR REGRESSION equation, and little or no theoretical and subject knowledge basis for choosing one variable over another, automated methods have been developed for choosing which variables to include in the regression. Stepwise regression is a class of model-building ALGORITHMS that incrementally includes or excludes variables based on how much they contribute to fitting the dependent variable of the regression. Although data-driven automatic MODEL selection procedures are available in most statistical software packages and may seem attractive, a model chosen by the stepwise procedure will, in general, lack optimality properties and fail to provide correct statistical inference. A stepwise-selected model generally will not be the correct model, nor the

best fitting model, nor the model that provides good out-of-sample predictions.

There are a variety of stepwise algorithms, but each follows the same basic logic. The stepwise algorithm incrementally chooses whether to include a variable or set of variables into a regression based on the variable's contribution to a particular fit criterion. The most common criterion for linear additive models is the minimization of the residual sum of squares (RSS) at each step. More general approaches have been developed with a similar logic based on log-likelihood statistics for use with CATEGORICAL and other types of data. The search for a "better" model is stopped, and the final model is thus chosen when a predetermined maximum number of variables have been selected, or the fit of the model is changed by less than a predetermined threshold when including or excluding additional variables.

The two most common implementations are forward selection and backward selection. Forward selection is more often used when the number of potential regressors (k) is close to or exceeds the number of observations in the data set (n). In forward selection, an initial model is usually fit with only the mean,

$$Y_i = \beta_0 + e_i$$

and at each subsequent p th step, one variable $x_{(p)}$ from among the remaining explanatory potential regressors ($x_1, x_2, \dots, x_k$) is added,

$$y_i = \beta_0 + \beta_1 x_{(1)i} + e_i$$

$$\dots$$

$$y_i = \beta_0 + \beta_1 x_{(1)i} + \beta_2 x_{(2)i} + \dots + \beta_p x_{(p)i} + e_i.$$

Using LEAST SQUARES to estimate the parameters, $\hat{\beta}_j$, the RESIDUAL SUM OF SQUARES with p variables is

$$RSS_p = \sum_{i=1}^n \left(y_i - \hat{\beta}_0 - \sum_{j=1}^p \hat{\beta}_j x_{(j)1} \right)^2.$$

At the p th step, each of the $k - p - 1$ remaining excluded variables is added to the current model individually, and the RSS from these $k - p - 1$ regressions is retained. The variable that is added to the regression equation is the one that induces the greatest incremental change in the residual sum of squares,

$$F = \frac{RSS_{p-1} - RSS_p}{RSS_p / (n - p - 2)}.$$

Descriptions of stepwise regression may alternatively state that the procedure uses one of the following

equivalent ranking criteria, selecting a variable that (a) increases R^2 the most, (b) has the largest t -statistic, or (c) has the largest partial correlation with the dependent variable. Variables are usually added until either there are no more variables with a significant F statistic that remain to be added, or a user-selected upper bound on the number of variables (p) is reached. Note that in the context of a stepwise search, the F statistic is not actually drawn from an F DISTRIBUTION.

Backward selection does essentially the reverse of forward selection, starting with a full set of variables included in the regression, and then sequentially eliminating the variable that, equivalently, (a) decreases R^2 the least, (b) has the smallest F or t -statistic, or (c) has the smallest partial correlation with the dependent variable. Once eliminated, a variable is not subsequently reconsidered for inclusion in the model. Note that if the number of observations is less than the number of variables, including all variables in a regression is not feasible. In the case of $n < k$, either the backward selection procedure must be abandoned or the researcher must make an initial choice of eliminating at least $k - n - 1$ variables prior to beginning the algorithm.

Stepwise regression fails as a tool for model selection for both theoretical and practical reasons. With respect to the final model that is chosen by stepwise regression, the method invalidates much of the standard theory for statistical inference when the same data are used for model building/selection and HYPOTHESIS TESTING (Miller, 1990). In particular, the parameter estimates on the selected variables will be biased upwards in magnitude because of the SELECTION BIAS of the procedure. Inference based on the selected model is also incorrect because the CONFIDENCE INTERVALS on coefficients will be too small, and F tests on subsets of parameters will be artificially significant because the variance of the residuals will be underestimated. Moreover, not only will stepwise regression generally fail to find the correct model that generated the data, but stepwise regression is not even likely to find the best fitting model! The problems associated with stepwise regression are minimized in the rare case where all the potential regressors are orthogonal to one another, and the problems are exacerbated as the CORRELATION between variables increases.

There are alternatives to relying on stepwise regression to sift through large numbers of competing explanatory variables. If multiple explanatory variables are believed to be manifestations of a small

number of common latent measures, then it is better to include summaries of these latent measures as explanatory variables in the regression. For example, it is possible to reduce the dimensionality of multiple explanatory variables by using only their PRINCIPAL COMPONENTS as REGRESSORS. If groups of explanatory variables exist that each represent competing theories, then it is better to formulate non-nested hypothesis tests to directly assess the significance of the difference between the competing theories. It is better to let theory and substantive knowledge of the data guide model building instead of relying on generally misleading automated procedures such as stepwise regression.

STOCHASTIC

Variables whose values cannot be fully controlled or determined are stochastic. If a variable measures the outcomes of N trials of an experiment, it is a stochastic variable if the outcomes cannot be entirely determined or predicted prior to observation. The random variation in outcomes is due to chance, and hence, stochastic variables are defined with probability distributions rather than with exact or deterministic functions. More generally, a stochastic dependent variable, $y = g(\mathbf{X}) + \varepsilon$, is composed of a deterministic function, $g(\mathbf{X})$, which could be simply a constant, and a stochastic disturbance or ERROR term, ε .

SIGNIFICANCE

Stochastic is a fundamental concept in social science methodology because all causal processes (dependent variables) are assumed to be stochastic. In the natural sciences, causal relationships are exact rather than stochastic, so researchers can calculate the PARAMETERS that define a relationship by constructing a controlled experiment and running trials that cover the full range of values taken by the explanatory variables. When the causal relationship is exact, trials of the experiment are points on the deterministic function rather than a sample drawn from the PROBABILITY DISTRIBUTION centered on that function, because there

is no SAMPLING ERROR if the dependent variable is not stochastic. In contrast, researchers in the social sciences must use QUASI-EXPERIMENTS, face greater limitations in MEASUREMENT, and investigate more complex causal processes involving human behavior rather than the interaction of physical elements. In turn, all causal processes in the social sciences are assumed to be stochastic in nature and hence must be investigated through SAMPLING and STATISTICAL INFERENCE. Consider the implication of this assumption for predicting values of a stochastic dependent variable, $y = g(\mathbf{X}) + \varepsilon$. Even if the deterministic part, $g(\mathbf{X})$, is known, prediction is still made with ERROR because the stochastic component, ε , causes the values of the dependent variable to vary around the conditional mean of y given $\mathbf{X}$, defined by $g(\mathbf{X})$.

The assumption that all dependent variables are stochastic is generally justified in three ways. First, the stochastic disturbance accounts for the omission of innumerable minor, idiosyncratic factors. The net effect of these omitted factors on the dependent variable is assumed to vary randomly across observations. Second, dependent variables in the social sciences are generally, if not always, measured with ERROR. Third, human behavior is inherently RANDOM. Factors ranging from incomplete information to strategic behavior complicate decision making in economic, political, and social contexts and thereby prevent people from behaving in a purely deterministic manner. This justification is often the basis for arguing that all populations in the social sciences are infinite, because even history is a sample of all possible histories if human behavior is stochastic.

Explanatory variables are often assumed to be nonstochastic or fixed in repeated samples. When explanatory variables are stochastic, the crucial issue is whether they are correlated with the disturbance. If correlated, they produce BIASED PARAMETER ESTIMATES. If uncorrelated, the explanatory variables represent ancillary REGRESSORS (i.e., the marginal probability distributions of the regressors do not depend on the parameters of interest). In the context of dynamic models, this condition is labeled weak EXOGENEITY. When stochastic regressors are ancillary or weakly exogenous, conditioning on their observed values allows them to be treated as fixed.

HISTORY

The word *stochastic* comes from the Greek word *stokhos*, meaning “a bull’s eye” or target. The process

of throwing darts produces stochastic outcomes that could be modeled as a probability distribution with the bull's eye at the center. Formal theorizing about stochastic outcomes began with a series of exchanges between Blaise Pascal and Pierre Fermat in 1654 about the game of dice, which established some fundamental concepts in PROBABILITY theory. Development of the theory of stochastic processes, however, did not begin until the early 1900s, when Andrei Markov proposed the concept of the MARKOV CHAIN. The Markov chain is a sequence of random variables in which the value (state) of the future variable is determined by the value (state) of the present variable but is independent of the process by which the value (state) of the present variable arose from the values (states) of previous variables in the sequence. Extension of this concept from a discrete to a continuous state space (set of possible variable values) defines a general stochastic process (also called a Markov process).

APPLIED EXAMPLES

Consider the random event of flipping a coin, where H and T denote the two possible outcomes. Given a fair coin, the two events are equally likely, $P(H) = P(T) = 0.5$. Yet knowing the probability distribution for the outcomes of this event does not enable one to predict the outcome of any trial with certainty. Suppose p_N is the fraction of N trials for which the outcome is H . For $N = 6$, the likelihood that p_N equals the true parameter, $\pi = 0.5$, is only 31.25%. The stochastic nature of this event causes p_N to vary around its true value, π , thereby preventing calculation of the parameter and requiring the use of statistical inference.

Consider another example in the context of REGRESSION analysis. Suppose the causal process of interest is modeled as a linear function of a set of exogenous variables and a stochastic disturbance, $y = \mathbf{X}\beta + \varepsilon$, where $\mathbf{X}$ is the matrix of exogenous variables, β is the vector of unknown parameters, and ε is the disturbance. The deterministic part of the relationship is $\mathbf{X}\beta$, whereas ε represents the stochastic part. Regression analysis uses sample data to estimate β , which involves decomposing the variation of y into its explained part attributable to $\mathbf{X}$ (i.e., variation of the deterministic function) and its unexplained part attributable to ε (i.e., variation of the stochastic disturbance). As functions of the dependent variable, the estimator of β is a stochastic variable with a SAMPLING DISTRIBUTION, and predictions about the value of y given $\mathbf{X}$ are made with

ERROR due to uncertainty attributable to the stochastic disturbance as well as the joint estimation of the parameters. In order to simplify statistical inference, assumptions are often imposed on the probability distribution of the stochastic disturbance as part of ORDINARY LEAST SQUARES estimation.

STRATIFIED SAMPLE

Often, SURVEY samples are designed in a way that takes into account knowledge about the POPULATION structure. This may involve an attempt to ensure that the SAMPLE has the same structure as the population in important respects or an attempt purposively to deviate from the population structure in order to increase the representation of certain subgroups. Such sample designs are referred to as *stratified sampling*, and the outcome of implementing the design is a *stratified sample*.

There are two types of stratified sampling: proportionate and disproportionate. Proportionate stratified sampling involves controlling the sample proportions in each stratum to equal the population proportions. If the strata are correlated with the survey measures, this will have the effect of increasing the precision of survey estimates (see DESIGN EFFECTS). Proportionate stratification can be achieved by either creating explicit strata and sampling independently from each, or sorting the SAMPLING FRAME units into a meaningful order and then sampling systematically from the ordered list (see SYSTEMATIC SAMPLING). These methods are known, respectively, as “explicit stratified sampling” and “implicit stratified sampling.” Proportionate stratification cannot have an adverse effect on the precision of estimates. The worst scenario is that strata turn out to have zero correlation with a particular survey measure, in which case stratification has no effect on precision and the sample is equivalent to a simple random sample (see SIMPLE RANDOM SAMPLING). Selection probabilities are not affected by proportionate stratification, so no BIAS can be introduced by a poor choice of strata.

Disproportionate stratification involves applying different sampling fractions (see SAMPLING FRACTION) in different strata. The objective is often to increase the sample size of one or more important subgroups for which separate estimates are required. In this situation, disproportionate stratification typically reduces the precision of estimates relating to the total study population (see DESIGN EFFECTS), but increases the precision of estimates for the oversampled stratum or strata. Disproportionate stratification can, however, also be used to *increase* the precision of total population estimates in situations where inherent variability differs greatly between the strata and can be estimated in advance. In such situations, precision is maximized by use of Neyman optimum allocation:

$$\frac{n_h}{N_h} \propto \frac{s_h}{\sqrt{C_h}}. \quad (1)$$

The optimum allocation rule states that the sampling fraction in stratum h , $\frac{n_h}{N_h}$, should be set proportional to the stratum standard deviation, s_h , and inversely proportional to the square root of the unit cost of data collection in the stratum, C_h .

In quantitative surveys, the choice of proportionate or disproportionate sampling is an important and explicit part of the design. In QUALITATIVE studies, there is no attempt to quantify the relationship between sample and population, so the distinction between proportionate and disproportionate sampling is not relevant. But a sample can still be said to be stratified if it has been designed deliberately to reflect certain aspects of population structure.

STRENGTH OF ASSOCIATION

The strength of association shows how much two variables COVARY and the extent to which the INDEPENDENT VARIABLE affects the DEPENDENT VARIABLE.

In summarizing the relationship between two VARIABLES in a single summary STATISTIC, the strength of the association is shown by a value between 0

and 1. The larger the absolute value of the association measure, the greater the association between the variables. A value of 1 signifies a perfect association between the variables according to the association model that is being used. A value of 0 shows that there is a NULL relationship between the variables. Negative values for ordinal and numeric data occur when larger values of one variable correspond to smaller values of the other variable.

The strength of association between two variables corresponds to the TREATMENT difference in EXPERIMENTS. As such, it can be measured using ASYMMETRIC MEASURES, although it is more commonly measured with symmetric COEFFICIENTS whose value is the same regardless of which variable is the independent variable.

Many statistical measures of RELATIONSHIP have been proposed, and they differ in their assessment of strength of association. The “gold standard” is PEARSON’S R for numeric data, whose squared value shows the proportion of variance in one variable that can be accounted for by LINEAR prediction from the other variable. Several measures for non-numeric variables can similarly be interpreted as PROPORTIONAL-REDUCTION-IN-ERROR measures (Costner, 1965). Whereas some of these measures attain their maximum value of 1 when there is a strong MONOTONIC relationship between the variables, others (such as YULE’S Q) require only a weak monotonic relationship, as when larger values on one variable correspond to equal or larger values on the other variable.

Pearson’s r interprets statistical INDEPENDENCE as the condition for no relationship, as do such other coefficients as Goodman and Kruskal’s TAU and Yule’s Q . Weisberg (1974) distinguishes other null conditions for some coefficients. The LAMBDA COEFFICIENT for nominal variables, for example, has a value of 0 when the modal category on the dependent variable is the same for every category of the independent variable.

There are no strict criteria for evaluating whether an association is large or small, although relationships above .70 are usually considered large, and those below .30 are usually considered small.

The strength-of-association concept can be generalized to more than two variables. For example, a CANONICAL CORRELATION shows the strength of association between two sets of variables. The R -SQUARED statistic shows the strength of association represented by a REGRESSION EQUATION.

STRUCTURAL COEFFICIENT

The term *structural coefficient* is used in discussions of PATH ANALYSIS and STRUCTURAL EQUATION MODELING (Duncan, 1975) to contrast it from the term *regression coefficient*, typically used in discussions of regression analysis. To motivate the term, it is often useful to represent the set of structural equations in the form of a *path diagram*. Figure 1 shows the path diagram for a student-level model of science achievement. This figure was used in Kaplan (2000) to motivate the discussion of path analysis. Path diagrams are especially useful pictorial devices because, if drawn accurately, then there is a one-to-one relationship between the diagram and the set of structural coefficients.

The system of structural equations representing the model in Figure 1 can be written as

$$\mathbf{y} = \boldsymbol{\alpha} + \mathbf{B} \mathbf{y} + \boldsymbol{\Gamma} \mathbf{x} + \boldsymbol{\zeta}. \quad (1)$$

where $\mathbf{y}$ is a vector of observed endogenous variables, $\mathbf{x}$ is a vector of observed exogenous variables, $\boldsymbol{\alpha}$ is a vector of structural intercepts, $\mathbf{B}$ is a structural coefficient matrix that relates endogenous variables to each other, $\boldsymbol{\Gamma}$ is a structural coefficient matrix that relates endogenous variables to exogenous variables, and $\boldsymbol{\zeta}$ is a vector of disturbance terms where $\text{Var}(\boldsymbol{\zeta}) = \boldsymbol{\Psi}$ is the covariance matrix of the disturbance terms. Finally, let $\text{Var}(\mathbf{x}) = \boldsymbol{\Phi}$ be the covariance matrix for the exogenous variables.

The elements in $\mathbf{B}$ and $\boldsymbol{\Gamma}$ are the structural coefficients representing the relationships among the variables. The pattern of zero and nonzero elements in these matrices, in turn, are imposed by the underlying substantive theory. For example, in the model shown in Figure 1, a structural coefficient in $\mathbf{B}$ would be the path relating science achievement at grade 10 (SIGRA10) to the extent to which students find their work in the science class challenging (CHALLG). A

Figure 1 Education Indicators Model: Initial Specification

SOURCE: Kaplan (2000).

structural coefficient in $\boldsymbol{\Gamma}$ would be the path relating SIGRA10 to socioeconomic status (SES).

We can distinguish between three types of structural coefficients in $\mathbf{B}$ and $\boldsymbol{\Gamma}$. The first type are those that are to be estimated. These are often referred to as *free* parameters. Thus, in the model in Figure 1, the observable paths are the free parameters.

The second set of parameters is the parameters that are given a priori values that are held constant during estimation. These parameters are often referred to as *fixed* parameters. Most often, the fixed parameters are set equal to zero to represent the absence of the relationship. Again, considering the model in Figure 1, we theorize that there is no direct relationship between science achievement (SCIACH) and SES. Thus, the structural coefficient is fixed to zero. Finally, it is possible to constrain certain parameters to be equal to other parameters in the model. These elements are referred to as *constrained* parameters. An example of constrained parameters would be requiring that the effect of SCIGRA6 on SIGRA10 be the same as the effect of SES on SIGRA10.

Three additional features of structural coefficients are worth noting. First, as with regression coefficients in general, structural coefficients can be tested for significance. Second, when the structural coefficients are standardized, they are referred to as path coefficients (Duncan, 1975; Wright, 1934). Third, structural coefficients can be multiplied and added together to form coefficients of indirect and total effects (Duncan, 1975).

STRUCTURAL EQUATION MODELING

Structural equation modeling (SEM) can be defined as a class of methodologies that seeks to represent hypotheses about the means, variances, and covariances of observed data in terms of a smaller number of “structural” parameters defined by a hypothesized underlying conceptual or theoretical model. Historically, structural equation modeling derived from the hybrid of two separate statistical traditions. The first tradition is factor analysis, developed in the disciplines of psychology and psychometrics. The second tradition is simultaneous equation modeling, developed mainly in econometrics, but having an early history in the field of genetics and introduced to the field of sociology under the name PATH ANALYSIS. A more detailed discussion of the history of structural equation modeling can be found in Kaplan (2000).

THE GENERAL MODEL

The general structural equation model, as outlined by Jöreskog (1973), consists of two parts: (a) the structural part linking latent variables to each other via systems of simultaneous equations, and (b) the measurement part linking latent variables to observed variables via a restricted (confirmatory) factor model. The structural part of the model can be written as

$$\eta = \alpha + B\eta + \Gamma\xi + \zeta, \quad (1)$$

where η is a vector of endogenous (criterion) latent variables, α is a vector of structural intercepts, ξ is a vector of exogenous (predictor) latent variables, B is a matrix of regression coefficients relating the latent endogenous variables to each other, Γ is a matrix of regression coefficients relating endogenous variables to exogenous variables, and ζ is a vector of disturbance terms.

The latent variables are linked to observable variables via measurement equations for the endogenous variables and exogenous variables. These equations are defined as

$$y = \Lambda_y\eta + \epsilon, \quad (2)$$

and

$$x = \Lambda_x\xi + \delta, \quad (3)$$

where Λ_y and Λ_x are matrices of factor loadings, respectively, and ϵ and δ are vectors of uniqueness, respectively. In addition, the general model specifies variances and covariances for ξ , ζ , ϵ , and δ , denoted as Φ , Ψ , Θ_ϵ , and Θ_δ , respectively. A path diagram of a prototypical structural equation model is given in Figure 1.

Structural equation modeling is a methodology designed primarily to test substantive theories. As such, a theory might be sufficiently developed to suggest that certain constructs do not affect other constructs, that certain variables do not load on certain factors, and that certain disturbances and measurement errors do not covary. This implies that some of the elements of B , Γ , Λ_y , Λ_x , Φ , Ψ , Θ_ϵ , and Θ_δ are *fixed* to zero by hypothesis. The remaining parameters are *free* to be estimated. The pattern of fixed and free parameters implies a specific structure for the covariance matrix of the observed variables. In this way, structural equation modeling can be seen as a special case of a more general *covariance structure model* defined as $\Sigma = \Sigma(\Omega)$, where Σ is the population covariance matrix, and $\Sigma(\Omega)$ is a matrix-valued function of the *parameter vector* Ω containing all of the parameters of the model.

IDENTIFICATION OF STRUCTURAL EQUATION MODELS

A prerequisite for the estimation of the parameters of the model is to establish whether the parameters are *identified*. A definition of *identification* can be given by considering the problem from the covariance structure modeling perspective. The population covariance matrix Σ contains population variances and covariances that are assumed to follow a model characterized by a set of parameters contained in Ω . We know that the variances and covariances in Σ can be estimated by their sample counterparts in the sample covariance matrix S using straightforward formulae for the calculation of sample variances and covariances. Thus, the parameters in Σ are identified. What needs to be

Figure 1 Structural Equation Model of Science Achievement Model
SOURCE: Kaplan (2000).

established prior to estimation is whether the unknown parameters in Ω are identified from the elements of Σ .

We say that the elements in Ω are *identified* if they can be expressed uniquely in terms of the elements of the covariance matrix Σ . If all elements in Ω are identified, then the model is identified. A variety of necessary and sufficient conditions for establishing the identification of the model exist and are described in Kaplan (2000); among these are the rank and order conditions of identification that came out of the econometric tradition.

ESTIMATION OF STRUCTURAL EQUATION MODELS

The problem of parameter estimation in structural equation modeling concerns obtaining estimates of the free parameters of the model, subject to the constraints imposed by the fixed parameters of the model. In other words, the goal is to apply a model to the sample covariance matrix S , which is an estimate of the population covariance matrix Σ that is assumed to follow a structural equation model. Estimates are obtained such that the discrepancy between the estimated covariance matrix $\hat{\Sigma} = \Sigma(\hat{\Omega})$ and the sample covariance matrix S is as small as possible.

Parameter ESTIMATION requires choosing among a variety of *fitting functions*. Fitting functions have the properties that (a) the value of the function is greater than or equal to 0; (b) the value of the function equals 0 if, and only if, the model fits the data perfectly; and (c) the function is continuous. Estimation can be conducted under the assumption of multivariate normality of the observed data such as MAXIMUM LIKELIHOOD ESTIMATION, or under more relaxed assumptions regarding the distribution of the data such as general weighted least squares estimation for continuous non-normal and/or categorical data.

TESTING

Once the parameters of the model have been estimated, the model can be tested for global fit to the data. The null hypothesis states that the specified model holds in the population. The corresponding alternative hypothesis is that the population covariance matrix is any symmetric (and positive definite) matrix. Under maximum likelihood estimation, the statistic for testing the null hypothesis that the model fits in the population is referred to as the LIKELIHOOD RATIO (LR) TEST. The large sample distribution of the likelihood ratio test is chi-square with degrees of freedom given by the

difference in the number of nonredundant elements in the population covariance matrix and the number of free parameters in the model.

In addition to a global test of whether the model holds exactly in the population, one can also test hypotheses regarding the individual fixed and freed parameters in the model. These include the Lagrange multiplier test (also referred to as the modification index) and the Wald test. The former examines whether freeing a fixed parameter will improve the fit of the model, whereas the latter examines whether fixing a free parameter will degrade the fit of the model. Strategies for the use of these methods have been described in Saris et al. (1987) and Kaplan (1990).

Alternative Methods of Model Fit

For more than 20 years, attention has focused on the development of alternative indexes that provide relatively different perspectives on the fit of structural equation models. The development of these indexes has been motivated, in part, by the known sensitivity of the likelihood ratio chi-square statistic to large sample sizes. In this case, indexes have been developed that compare the fit of the proposed model to a baseline model of complete independence of the variables, including indexes that add a penalty function for estimating too many parameters. Examples include the non-normed fit index and the comparative fit index. Other classes of indexes have been motivated by a need to rethink the notion of testing exact fit in the population—an idea deemed by some to be unrealistic in most practical situations. The index available that tests approximate fit in the population is the root mean square error of approximation. Finally, another class of alternative indexes has been developed that focuses on the cross-validation adequacy of the model. Examples include the Akaike Information Criterion and the Expected Cross Validation Index. The use of these indexes is not without some degree of controversy (e.g., see Kaplan, 2000; Sobel & Bohrnstedt, 1985).

STATISTICAL ASSUMPTIONS UNDERLYING SEM

As with all statistical procedures, structural equation modeling rests on a set of underlying assumptions. The major assumptions associated with structural equation modeling include multivariate normality, no systematic missing data, sufficiently large sample size, and correct model specification.

Multivariate Normality

A basic assumption underlying the standard use of structural equation modeling is that observations are drawn from a continuous and multivariate normal population. This assumption is particularly important for maximum likelihood estimation because the maximum likelihood estimator is derived directly from the expression for the multivariate normal distribution. If the data follow a continuous and multivariate normal distribution, then maximum likelihood attains optimal asymptotic properties—namely, that the estimates are normal, unbiased, and efficient.

The effects of non-normality on estimates, standard errors, and tests of model fit are well known. The extant literature suggests that non-normality does not affect parameter estimates. In contrast, standard errors appear to be underestimated relative to the empirical standard deviation of the estimates. With regard to goodness-of-fit, research indicates that non-normality can lead to substantial overestimation of likelihood ratio chi-square statistic, and this overestimation appears to be related to the number of degrees of freedom of the model.

Estimators for Non-Normal Data

One of the major breakthroughs in structural equation modeling has been the development of estimation methods that are not based on the assumption of continuous multivariate normal data. Browne (1984) developed an asymptotic distribution free (ADF) estimator based on weighted least squares theory, in which the weight matrix takes on a special form. Specifically, when the data are not multivariate normal, the weight matrix can be expanded to incorporate information about the skewness and kurtosis of the data. Simulation studies have shown reasonably good performance of the ADF estimation compared to maximum likelihood (ML) and GENERALIZED LEAST SQUARES (GLS); however, ADF suffers from computational difficulties if the model is large (in terms of degrees of freedom) relative to the sample size. These constraints have limited the utility of the ADF estimator in applied settings.

Another difficulty with the ADF estimator is that social and behavioral science data are rarely continuous. Rather, we tend to encounter categorical data, and often, we find mixtures of scale types within a specific analysis. When this is the case, the assumptions

of continuity as well as multivariate normality are violated. Muthén (1984) made a major contribution to the estimation of structural equation models under these more realistic conditions by providing a unified approach for estimating models containing mixtures of measurement scales.

Missing Data

Generally, statistical procedures such as structural equation modeling assume that each unit of analysis has complete data. However, for many reasons, units may be missing values on one or more of the variables under investigation. Numerous ad hoc approaches exist for handling missing data, including LISTWISE and PAIRWISE DELETION. However, these approaches assume that the MISSING DATA are unrelated to the variables that have missing data, or any other variable in the model, that is, missing completely at random (MCAR)—a heroic assumption at best. More sophisticated approaches for dealing with missing data derive from the seminal ideas of Little and Rubin (1987).

Utilizing the Little and Rubin framework, a major breakthrough in model-based approaches to missing data in the structural equation modeling context was made simultaneously by Allison (1987) and Muthén, Kaplan, and Hollis (1987). They showed how structural equation modeling could be used when missing data are missing at random (MAR), an assumption that is more relaxed than MCAR.

The major limitation associated with the Muthén et al. (1987) approach estimator is that it is restricted to modeling under a relatively small number of distinct missing data patterns. Small numbers for distinct missing data patterns will be rare in social and behavioral science applications. Recently, however, it has been possible to incorporate MAR-based approaches (Little & Rubin, 1987) to modeling missing data within standard SEM software in a way that mitigates the problems with the Muthén et al. approach. Specifically, imputation approaches have become available for maximum likelihood estimation of structural model parameters under incomplete data assuming MAR. Simulation studies have demonstrated the effectiveness of these methods in comparison to listwise deletion and pairwise deletion under MCAR and MAR. Maximum likelihood estimation under MAR is available in LISREL, AMOS, and Mplus.

Specification Error

Structural equation models assume that the model is properly specified. SPECIFICATION error is defined to be the omission of relevant variables in any equation of the system of equations defined by the structural equation model. This includes the measurement model equations as well as the structural model equations.

The mid-1980s saw a proliferation of studies on the problem of specification error in structural equation models. On the basis of work by Kaplan and others (summarized in Kaplan, 2000), the general finding is that specification errors in the form of omitted variables can result in substantial parameter estimate bias. In the context of sampling variability, standard errors have been found to be relatively robust to small specification errors. However, tests of free parameters in the model are affected in such a way that specification error in one parameter can propagate to affect the power of the test in another parameter in the model.

MODERN DEVELOPMENTS CONSTITUTING THE "SECOND GENERATION" OF STRUCTURAL EQUATION MODELING

Recent methodological developments have allowed traditionally different approaches to statistical modeling to be specified as special cases of structural equation modeling. The more important of these modern developments have resulted from specifying the general model in a way that allows a "structural modeling" approach to other types of analytic strategies. The most recent example of this development is the use of structural equation modeling to estimate multilevel data, including models that estimate growth in longitudinal studies and the combination of latent class and latent variable modeling.

Multilevel Structural Equation Modeling

In recent years, attempts have been made to integrate MULTILEVEL modeling with structural equation modeling so as to provide a general methodology that can account for issues of measurement error and simultaneity as well as multistage sampling.

Multilevel structural equation modeling assumes that the levels of the within-group endogenous and exogenous variables vary over between-group units. Moreover, it is possible to specify a model that is assumed to hold at the between-group level, and that explains between-group variation of the within-group

variables. An overview and application of multilevel structural equation modeling can be found in Kaplan (2000).

Growth Curve Modeling From the Structural Equation Modeling Perspective

GROWTH CURVE MODELING has been advocated for many years by numerous researchers for the study of interindividual differences in change. The specification of growth models can be viewed as falling within the class of multilevel linear models (Raudenbush & Bryk, 2002), where level-1 represents intra-individual differences in initial status and growth, and level-2 models individual initial status and growth parameters as a function of interindividual differences. Recent research has also shown how growth curve models could also be incorporated into the structural equation modeling framework utilizing existing structural equation modeling software. The advantage of the structural equation modeling framework to growth curve modeling is its tremendous flexibility in specifying models of substantive interest.

Finally, recent developments by Muthén (2002) and his colleagues have led to the merging of growth curve models and latent class models for purposes of isolating unique populations defined by unique patterns of growth. This methodology constitutes *growth mixture modeling*. Extensions of growth mixture modeling allow latent class membership to be predicted by characteristics of individuals—referred to as *general growth mixture modeling*.

STRUCTURAL LINGUISTICS

Structural linguistics studies language as a structure or system rather than a process. It formed the basis for the rapid development of STRUCTURALISM across the social sciences and humanities in the 1960s, and its influence can be traced through many philosophical and theoretical debates in the last decades of the 20th century.

The founder of structural linguistics was Ferdinand de Saussure. Writing around the same time as Durkheim, he treated language as a social fact—something that exists over and above the individual members of a linguistic community and imposes itself upon them. We cannot study or understand a language by looking at individual speech acts, which are unique and cannot be the object of a science. We have to look at the language that enables speech acts. Saussure argues that a language consists of a finite number of sounds and rules about the combination of these sounds, rather like the rules of grammar but working at a more fundamental level (Saussure 1974).

The basic unit of a language is the sign, made up of a *signifier*, the sound or marks on a piece of paper, and a *signified*, the concept. It is important to emphasize that the signified is the concept and not the object. The relationship between words and objects is conventional, not a matter of necessity, and we have to accept the

relationship, say, between the word “leg” and the long things at the end of (most of) our bodies if we wish to be part of our linguistic community. They could, in fact, be called anything. This breaks our common-sense relationship between words and things, and it contributed toward the “linguistic turn” in 20th-century social theory and philosophy.

The linguistic sign is combined with others into a system, and we can find the significant elements of a language by a method of *concomitant variation*, or varying each element until we find one that changes the meaning of the sign. For example, if we change the “c” in “cat” to “m,” we get a very different meaning and thus establish the opposition “c/m” as a significant one. These elements can be analyzed on two axes: the syntagmatic level, which concerns rules about what can follow what in a sentence, and the paradigmatic level, which concerns what can be substituted for what in a sentence.

This means that within the conventional system of language, each sign takes its meaning from its relationship to other signs; meaning does not exist *in* words but *between* words.

At its simplest, the structuralist movement involved the idea that the world we experience is the product of underlying structures. It was particularly useful in the analysis of cultural systems, varying from the huge project of Claude Lévi-Strauss’s (1969). *The Elementary Structures of Kinship* to William Wright’s (1975) analysis of the underlying narrative structures of different types of Western film.

STRUCTURALISM

Structuralism is rooted in the idea that language acquires its meaning from the juxtaposition of elements within a linguistic system. As an antecedent to the textual turn in the social sciences, structuralism lent a rigorous and objective character to the study of

culture by investigating the systemic rules and models underlying text. An emphasis on the social power of language to order individual speech and action is a hallmark of structuralist analysis. Although structuralism has been criticized for being antihumanistic and deterministic, its core insights have been incorporated into SEMIOTICS, POSTSTRUCTURALISM, POSTMODERNISM, and structuration theory.

Ferdinand de Saussure, the father of STRUCTURAL LINGUISTICS, suggested that the proper approach to language is to examine the underlying rules and models of the linguistic systems that make it possible for real-life speech to operate. Discounting the importance of both the historical evolution and the individual use of language, Saussure argued that language is a static system of collective rules (*langue*), rather than serial speech acts (*parole*). Moreover, the meaning of language is to be found in the relations among elements within the linguistic system, not in any extralinguistic considerations. These intellectual moves paved the way for the collective, systematic, rule-based study of languages and other aspects of culture.

A strong program for the autonomy of the cultural system, structuralism came to be regarded as an IDEALIST alternative to materialist perspectives such as Marxism. Anthropologists subsequently broadened the approach to encompass myth, religion, and kinship systems. Claude Lévi-Strauss found that myths could be probed for an underlying order structuring the narrative form and social life itself. Among the most significant methodological concepts is the binary opposition, a recurrent polarization of difference found in pairs of terms—such as male-female, raw-cooked, sacred-profane, purity-danger, and self-other—that Lévi-Strauss ultimately attributes to the structures of the mind itself. These oppositions impose an intelligible order on the basic data of experience through a principle of difference and exclusion. Irresolvable conflict between the binary terms motivates mythmaking, whose underlying purpose is to probe and resolve structural tensions.

A major development for structuralism was its metamorphosis into semiology, the science of signs. The key to this development was the realization that nonlinguistic systems could also be fruitfully analyzed using structuralist principles. The critic and philosopher Roland Barthes applied the principles of structuralism to a wide variety of Western cultural artifacts, notably fashion, eating, and wrestling. Barthes worked by isolating a system for study and then delineating the

semiotic codes through which the systems operate. In the case of fashion, Barthes argued that the semiotic logic of fashion constituted an autonomous “fashion system.”

Poststructuralist perspectives, underscoring contingency, action, and change within cultural systems, emerged in the 1960s partially as a criticism of structuralism’s deterministic view of culture. This acute critical reaction, whose principal contributors included Jacques Derrida (DECONSTRUCTIONISM) and Michel Foucault (genealogy), sought to understand the historical and social construction of language and signs. Poststructuralist insights into the structuring of structure were critically appropriated by Anthony Giddens and form the basis of his influential theory of structuration. Giddens makes the case that structure constrains agency while agency simultaneously gives reality to structure—a dynamic captured in the concept of practice. Structuralism’s orientation toward text and symbols also influenced postmodernism. For example, Jean Baudrillard’s explorations into the code of consumer culture owe a debt to the structuralist approach to meaning.

STRUCTURED INTERVIEW

A structured interview is an interview in which the questions the interviewers are to ask and, in many cases, the answer categories the respondents are to use have been fully developed and put in an INTERVIEW SCHEDULE before the interview begins. Structured interviews, sometimes also referred to as *standardized interviews*, are almost universally used in social SURVEYS designed to produce statistical descriptions of populations.

Structured interviews can be contrasted with SEMISTRUCTURED INTERVIEWS and UNSTRUCTURED INTERVIEWS. When an interviewer is conducting a semistructured interview, he or she has a list of topics or issues to be covered, but the specific wording of the questions is left to the interviewer. In addition, the interviewer is free to ask about additional topics or issues that were not anticipated in the interview outline. In an unstructured interview, interviewers are free during the interview to decide what topics to ask about, as well as how to word the specific questions.

The use of structured interviews is essential if the goal of the interviews is to produce statistical data. The answers to questions cannot be tabulated meaningfully unless all respondents answered the same question.

Example: Do you approve or disapprove of the way the President of the United States is doing his job?

A question similar to this is used routinely to tabulate the approval rating of presidents. Samples of people are asked this question, and the percentage of people saying they “approve” is calculated. The percent approving is tabulated over time to get a comparative sense of how people are feeling about the president, compared to other times in his administration and compared to other presidents.

Suppose, however, that some people were asked not about the president but about whether they approved or disapproved of the way the administration was conducting its affairs. Further suppose that some people were asked not whether they approved or disapproved, but whether they supported or opposed what the president was doing. These changes in wording would mean that people were generally being asked the same question, but research has shown that small changes in the wording of questions or answer categories can have a definite effect on the answers that are obtained. In short, if there was this kind of variation in the wording of questions that people answered, the tabulation of their answers would not be interpretable.

THE EVOLUTION OF STRUCTURED INTERVIEWS

In the early days of survey research, semistructured interviews were the norm. Interviewers were sent out with a list of topics, but they were free to devise their own questions to find out what people had to

say. Three considerations have led to the evolution of survey methods so that structured interviews are almost universally used:

1. Studies showed that small changes in the wording of questions or in the alternatives offered had discernible effects on the answers people gave.

2. When interviewers were free to decide on the wording of questions, not surprisingly they differed in the ways in which they worded questions to achieve the same objective. As a result, the answers obtained to surveys were often related to which interviewer did the interviewing.

3. When respondents were allowed to answer in their own words, it often was difficult to compare what they had to say. For example, if one respondent described her health as “not bad,” while another described her health as “fairly good,” could we reliably say that the first person’s health was better, worse, or about the same as that of the second person’s? Researchers have found that they can tabulate answers more reliably, and compare the answers of different respondents, if they have respondents choose from the same set of response alternatives.

Thus, in order to ensure that the differences in answers people give stem from differences in what they have to say, rather than differences in the questions they were asked or the way they chose to phrase their answers, researchers now routinely use structured interviews, in which both the wording of the questions and the response alternatives are designed ahead of time and are the same for all respondents.

STANDARDS FOR A STRUCTURED INTERVIEW

For semistructured and unstructured interviews, interviewers are free to adapt the wording of questions to the particular situation and to their perceptions of the characteristics of the respondents with whom they are talking. In a structured interview, the design of the interview schedule must create a set of questions and answers that will work “comfortably” for all respondents. This means that the design of the interview schedule must be carefully done; a structured interview schedule must meet numerous criteria in order to achieve its goals effectively:

1. The words have to be consistently understood, that is, understood in the same way by all respondents.

Questions that include unclear or ambiguous words, that can be interpreted in more than one way, will produce less good data because, in essence, some respondents will be answering different questions from others, depending on how they understand the question.

2. The questions should ask about things that all or almost all respondents can knowledgeably answer. If the interviewer is trying to collect information that people cannot recall or that they never had, the quality of the results will not be very good.

3. The wording of the questions needs to be such that interviewers can read the questions exactly as worded, without adding, subtracting, or changing words. If interviewers have to change the questions in order for them to be understood, in essence, different interviewers will be asking different questions, and the primary goal of the structured interview will be undermined.

4. Sequencing of the questions must produce a reasonable PROTOCOL for an interview interaction. The design of the instrument has to take into account the order of questions, so that respondents are not being asked the same question more than once and so that the interviewers know which questions do and do not apply to respondents.

5. When respondents are supposed to choose from a list of answers in order to answer a question, the answers need to fit the question; that is, they need to provide an exhaustive and mutually exclusive list of all the possible answers that someone might want to give.

6. Finally, if a structured interview is going to be administered in more than one language, the designers of the interview need to consider how well the questions and answers they write will translate into languages other than the original language.

INTERVIEWING PROCEDURES

A goal of structured interviews is to have the questions asked as consistently as possible for all RESPONDENTS. To accomplish this, interviewers are supposed to follow specific procedures when they conduct structured interviews:

1. They are to ask questions in the order in which they occur in the interview schedule, and they are to ask the questions exactly as they are worded.

2. When a respondent fails to answer a question completely, interviewers are to ask follow-up questions

(called nondirective PROBES) that do not increase the likelihood of one answer over others.

3. Interviewers record answers without discretion—that is, exactly as the respondent gives them.

4. Interviewers minimize personal or judgmental feedback, trying to create a professional relationship in which providing accurate answers is the priority.

TESTING A STRUCTURED INTERVIEW

Because a structured interview must meet so many standards, it is important to evaluate an interview schedule before using it in a full-scale survey. There are three kinds of evaluations that are often done:

1. Experts in the subject matter of the interview can provide input about whether or not the questions are the right ones and are covering the material that needs to be covered. Experts in survey question design often can provide information about questions that are likely to be confusing, difficult to answer, or difficult to administer in a standardized way. Experts in reading can review structured interview schedules to identify places where questions can be made clearer or simpler, or easier to understand. Bilingual reviewers can identify questions that are likely to be difficult to translate into other languages.

2. Cognitive testing of questions began to be widely done in the 1990s. Although cognitive testing takes many forms, the basic protocol is to ask respondents to answer some test questions. Then, respondents are asked to explain both how they understood the questions and how they went about answering the questions. Through this process, researchers can identify ambiguities in question wording, difficulties that respondents have in forming answers to questions, and the extent to which answers accurately reflect what respondents have to say.

3. Field pretest of structured interviews, prior to an actual survey, is the third main way that structured interview schedules are evaluated. Typically, experienced interviewers conduct structured interviews with respondents similar to those who will be included in the full-scale survey. Interviewer reports of problems with the questions constitute one way that question problems are identified. Another approach is to tape-record the pretest interviews, with respondent permission, and listen to those tapes to systematically tabulate the rates at which questions were read exactly as worded, the

rates at which respondents had trouble answering the questions, and the rates at which respondents asked for clarification.

Because interviewers are not free to change questions during interviews, it is particularly important to do a thorough job of testing structured interview schedules before they are used.

CONCLUSION

The evolution of structured interviews has been one of the important advances in survey research and the social sciences in the 20th century. The design and evaluation of structured interview schedules is among the most important elements in a well-conducted social science survey. The failure to carefully design and evaluate the questions in a structured interview before data collection can constitute one of the important sources of error and unreliability in surveys.

STRUCTURED OBSERVATION

Structured observation (sometimes also called *systematic observation*) is a technique for data collection that has two defining characteristics. First, it is part of the broad family of *observational* techniques in which the investigator(s) gather information directly without the mediation of respondents, interviewees, and so on. Second, it is a *structured* or *systematic* technique in which data are collected according to carefully defined rules and prearranged procedures. It can be applied to a variety of aspects of behavior and interaction in a wide variety of social settings. Like any observational technique, it is necessarily selective: The researcher is attempting to focus on those elements of the situation being observed that are relevant to particular investigatory purposes.

The directness of structured observation means that a researcher can gather data that subjects are unable to provide through other procedures, such as INTERVIEWS and QUESTIONNAIRES. This may be because of the nature and detail of the information being required (how many questions a teacher asks during a lesson, how many times someone interrupts during a conversation). It may be because of limited verbal skills (e.g., of young children). This directness also relates to the way that observation can take place in natural settings that have not been created for research purposes and that are not interrupted to allow measurements to be taken.

The structured nature of these observations derives from the use of OBSERVATION SCHEDULES through which observations are recorded according to carefully predefined criteria as categories of variables that can then be used for statistical analysis. These variables and categories must be explicitly defined so that different observers can use them in identical ways, and so that the variation in accounts arising from the particular interests and perceptions of different observers is eliminated. It is in this limited but important sense that structured observation can be described as an objective approach to data collection. The focus of the study and design of the instruments are influenced by the interests and values of the researcher in the same way as any other type of study. However, the process of data collection is independent of these values and interests, and the way in which the variables have been operationalized is open and available for scrutiny. Structured observation is usually most successful as an approach when it employs low-inference measures of an essentially factual nature and involves little observer judgment and interpretation. High-inference measures, such as those involving rating scales and incorporating judgments and evaluations by the observer, are far less likely to be reliably operationalized.

LOCATING OBSERVATIONS IN TIME

A key element of structured observation is that the data incorporate a time dimension: Observations are coded in real time and can be analyzed in terms of various temporal features. There are four kinds of time-related information that investigators may wish to consider:

1. Duration: the total amount of time taken up by a category of behavior
2. Frequency: the number of individual occurrences of a category of behavior

3. Location: the position of an occurrence within the day or week or observation session
4. Sequence: the way behaviors follow on from other behaviors

The extent to which each of these kinds of information is required will determine the kind of observation system employed.

INTEROBSERVER AGREEMENT

It is essential to ensure that all observers are using the schedule in the same way, and interobserver agreement is calculated by having two observers code the same events simultaneously. The simplest measure of interobserver agreement is the Smaller/Larger (S/L) index. When two observers have coded the same observation session, the lower count of frequency or duration is divided by the higher count. The resulting value can vary between 1 and 0. It is important to note that this index shows the extent to which the observers agree on overall occurrence but not necessarily that they agree on individual instances; that is, it shows marginal, not absolute, agreement. Therefore, it does not establish the clarity and explicitness of the observation schedule, although it can show that overall counts (but not necessarily the co-occurrence of categories of different variables) are estimated consistently.

A measure of absolute agreement is the Proportion Agreement Index (PAI). This is given by dividing the number of agreements on individual observations of a pair of observers by the total numbers of observations made. It has possible values between 1.0 (total agreement) and 0.0 (no agreement). The PAI is the most commonly used observer agreement index, and satisfactory levels generally have been suggested as 0.7 or 0.8. Some researchers correct this index for the fact that observers can agree on a code by chance even if they are using the schedule in different ways. These corrections and a fuller discussion of interobserver agreement are given by Croll (1986) and Suen and Ary (1989). In the case of long-term studies, it is important that investigators reestablish levels of interobserver agreement at regular intervals to guard against observer drift.

SOME PRACTICAL CONSIDERATIONS

Structured observation is a very resource-intensive approach to data gathering. Observation procedures need extensive development and pretesting, and

observers need careful training and monitoring. An important issue is that of REACTIVITY. Most structured observation studies aim to eliminate, or at least minimize, any influence of the process of observation on what is being observed. This frequently involves preliminary periods of fieldwork, when observers are present but not collecting data to be used in the analysis, that allow the subjects of the study to acclimatize to observer presence. Assessing reactivity may also involve debriefing of both observers and (at the end of the study) research subjects, incorporating responses to the observer as a category of the observation system. Traditionally, structured observation has been a pencil-and-paper technique in which observation sheets are completed live and later prepared for computer analysis with programs such as SPSS. Recently, however, systems have been developed for coding observation using handheld computers that can then be subjected to sophisticated analysis using dedicated software (e.g., Noldus, Trienes, Hendriksen, Jansen, & Jansen, 2000).

STRUCTURED, FOCUSED COMPARISON

Alexander L. George coined the expression “structured, focused comparison” to refer to a general method of theory development in qualitative, small-*N* research (George, 1979; see also George & McKeown, 1985; George & Smoke, 1974). The method is “focused because it deals selectively with only certain aspects of the historical case” (George, 1979, p. 61), and it is “structured because it employs general questions to guide the data collection and analysis in that historical case” (p. 62).

Structured, focused comparison was developed in reaction to what George saw as the shortcomings of CASE STUDY research. He argued that case study research often is not guided by clear theoretical objectives, and its idiosyncratic emphases provide a weak basis for producing cumulative knowledge. By contrast, structured, focused comparison encourages analysts to ask a set of “standardized, general questions” across cases. Regarding standardization, researchers use controlled comparisons “to assure the acquisition of comparable data from the several cases” (George, 1979, p. 62). This approach allows researchers to systematically collect comparable data for variables across two or more cases. Regarding general questions, researchers conceptualize variables at a high enough level of abstraction to be measured systematically across different cases. Only when such general concepts are employed can analysts hope to ask questions that apply to multiple cases. At the same time, however, the use of standardized, general questions does not mean that analysts cannot also inquire about the specific features of particular cases.

Structured, focused comparison was employed most explicitly in the field of international relations. George used it effectively in his work on international deterrence, showing that at least three different patterns of deterrence failure characterized international crises (George & Smoke, 1974). These patterns were discovered through a close analysis of actual cases of international crisis. George’s conclusions about the complex causes of deterrence failure challenged other theories that did not take seriously case-based evidence, including rational deterrence theory. More recently, a number of George’s students and other scholars have used these methods in their work, including Walt (1987) and Bennett (1999).

The call for structured, focused comparison paralleled a more general trend in the social sciences away from single case studies toward small-*N* research designs. Although the expression “structured, focused comparison” is used less commonly today, especially outside of international relations theory, the general concern with codifying rigorous procedures for qualitative studies focused on a small number of cases has been widely embraced. Contemporary small-*N* methodologists often describe their work as employing “systematic and contextualized comparisons,” which corresponds closely to George’s original formulation.

SUBSTANTIVE SIGNIFICANCE

Substantive significance refers to whether an observed effect is large enough to be meaningful. The concept of substantive significance was developed because statistical SIGNIFICANCE TESTS can find that very small effects are significant, even they are too small to matter. Substantive significance (also called *practical significance*) instead focuses on whether an observed RELATIONSHIP, difference, or coefficient is big enough to be considered important. Substantive significance is usually gauged intuitively, with different standards in different substantive realms.

For example, one way to think about the substantive significance of a difference between two percentages is in terms of how large that difference could possibly be. The largest possible difference in recidivism rates between prisons using two different prisoner release procedures would be 100%. Finding a difference in recidivism rates of 40% or 50% or 60% would likely be considered substantively significant, whereas obtaining a difference of 2% or 3% or 4% would likely be considered unimportant even if it passes the usual statistical significance tests.

Another way to think about substantive significance is as a comparison with the maximum possible difference from a mean level. If the mean recidivism rate is 30%, for example, at most it could be lowered by these 30%. An improvement of less than 10% of that ($.10 \times .30 = 3\%$) might be considered too small to matter, regardless of whether it is statistically significant. In some fields, researchers are expected to

specify in advance how large an effect they require for substantive significance.

STATISTICAL SIGNIFICANCE tests were developed to test whether effects obtained in small SAMPLES are likely to be real. When applied to large samples, however, statistical significance tests can find that very small effects are significant. For example, a difference of .01% (e.g., 12.23% under one experimental condition versus 12.24% under another condition) might be found to be significant when the number of CASES is in the hundreds of thousands. However, such a small difference is not likely to matter in most substantive realms. Hence, the concept of substantive significance was devised to call attention to the fact that statistical significance does not suffice. Thus, the substantive significance criterion is more stringent than the notion of statistical significance, rejecting the importance of some relationships that would pass conventional significance tests.

A similar logic holds for gauging the importance of relationships. A CORRELATION of .03 would be statistically significant if it were based on several thousand observations, but it might not be large enough to be considered substantively important in many application fields.

Fowler (1985) argues that one safeguard against reporting a statistically significant but trivial effect is to test a NULL HYPOTHESIS that specifies a nonzero effect. If the null hypothesis specifies the minimum EFFECT SIZE considered substantively important, then significance testing checks whether the observed effect is significantly greater than that minimum effect size.

SUM OF SQUARED ERRORS

Many statistical methods make use of sums of squares of various kinds; one of these is the sum of squared ERRORS (SSE). Another name used for this SUM OF SQUARES is the RESIDUAL SUM OF SQUARES. The sum is often abbreviated to terms such as SSE, ESS, RSS, and SSR, where SS stands for sum of squares, E for error, and R for RESIDUAL.

The term has its origin in measurements of simple physical quantities such as lengths or weights. When such measurements were repeated, people typically did not get the same value as from the previous measurement. It was believed that the item had one fixed, true, and perhaps unknown value, and the deviation of one measurement from another was due to errors in the measurements.

Let the true value of an item be denoted μ and the i th measurement y_i . The deviation $y_i - \mu$ of the observation from the true value then becomes the error in the measurement. The magnitude of this difference may not be known, but it is still useful to think in terms of errors when measurements vary from one replication to the next.

This line of reasoning is useful when trying to answer the question of how well a statistical model, such as REGRESSION or ANALYSIS OF VARIANCE, fits the data at hand. From such a model, it is possible to compute a predicted value of the dependent variable from the observed values of the independent variables and the estimated parameter values. The difference of the observed value from the predicted value is thought to measure the error produced by the model, borrowing the “error” term from its earlier measurement meaning. For simple regression, such an error term can be expressed as

$$e_i = y_i - \hat{y}_i = y_i - a - bx_i.$$

The letter e obviously stands for error, the two y values are the observed and predicted values of the dependent variable for the i th observation, a is the estimated intercept, b is the estimated slope of the regression line, and the x value is the value of the independent variable for this individual. Similar errors can be computed for many statistical models.

Next, we want an overall sense of the magnitudes of these errors. However, the sum of the errors will equal zero, because the positive and negative errors cancel out in the sum needed for the mean. We could take the absolute value of each error, such that all the errors become positive and find that sum, and use the mean or median of these absolute values. Mathematically, absolute values are not as simple to work with as squares. The choice was made to square each error, to make each term positive, and add these squares. This gives us the so-called *error sum of squares*.

A more modern term for error is *residual*. The difference between an observed and predicted value is thought to be due to the net effect of all other variables

not included in the *sampled* data, and there is nothing “wrong” with this difference. Thus, we get the residual sum of squares instead of the error sum of squares.

SUM OF SQUARES

Many statistical computations involve computations of sums of squares of one kind or another. Such sums are mainly used for two different purposes: to measure how different observations within a set are from each other, or as a tool in the estimation of population parameters. As the name implies, a sum of squares is a sum of squared numbers. For example, the sum of squares of the numbers 1, 2, 3, and 4 equals $1^2 + 2^2 + 3^2 + 4^2 = 30$.

When sums of squares are used to measure how different observations within a set are from each other, we usually subtract the MEAN of the observations from each observation, square the differences, and add the squares. The four observations above have a mean of 2.5; the differences become $1 - 2.5 = -1.5$, -0.5 , 0.5 , and 1.5 . When these differences are squared and added, we get the sum of squares of 5.00. This, then, is how different the four observations are from each other, as measured by the sum of squares. Such a sum of squares can be divided by its appropriate DEGREES OF FREEDOM (3) to get the VARIANCE ($s^2 = 1.67$) and thereby the STANDARD DEVIATION ($s = 1.29$) of the observations. Both of these statistics compensate for how many observations there are, and they can be compared across data sets with different numbers of observations. The reason the sum of squares for a dependent variable is not zero is because the variable has been affected by other variables.

Sums of squares are also used for the ESTIMATION of PARAMETERS, instead of the maximum likelihood method. The purpose with a sum of squares is to write the sum depending on both the data and unknown estimates of parameters. For example, the mean of the population from which the sample with observations 1, 2, 3, and 4 was taken ought to be somewhere in the middle of these observations. One way to find such a number is to ask what the value of the constant c should be in order for the sum of squares

$$(1 - c)^2 + (2 - c)^2 + (3 - c)^2 + (4 - c)^2$$

to be the smallest it can be.

For $c = 0$, we already know that the sum equals 30. But could there be some other value of c that gives a smaller sum? The trial approach, using different values of c , would be one approach. Another is to use differential calculus and find that c should be equal to the mean of the observations, here 2.5. Then, the sum of squares equals 5.00, and there is no other value of the constant that will result in a smaller sum of squares. Not surprisingly, using the sum of squares from the ORDINARY LEAST SQUARES method gives the sample mean as an estimate of the population mean.

More importantly, both analysis of variance and regression analysis make use of this least squares method to arrive at the familiar estimates for effect parameters in analysis of variance and for the coefficients in regression. For example, the formulas for the computation of slope and intercept in simple regression are found by minimizing the residual sum of squares:

$$\sum (y_i - a - bx_i)^2.$$

This calls for taking the derivatives of this mathematical function with respect to a and b , setting the resulting expressions equal to zero, and solving for a and b .

SUMMATED RATING SCALE. See
LIKERT SCALE

SUPPRESSION EFFECT

A traditional suppression effect in a two-PREDICTOR situation, according to Horst (1941), refers to an increase in prediction of a criterion (denoted as C) by including a predictor (denoted as S) that is completely unrelated to the criterion but is related to the other predictor (denoted as P). The first predictor is labeled as a suppressor, because it suppresses (or clears out) criterion-irrelevant variance in the second predictor. Specifically, a suppressor is “a variable, which increases the predictive validity of another variable (or set of variables) by its inclusion in a REGRESSION equation. This variable is a suppressor only for those variables whose regression weights are increased” (Conger, 1974, p. 36). In general, suppression effects tend to occur when there are high correlations among predictors.

Tzelgov and Henik (1991) further refined the above definition by stating that a predictor is considered a suppressor (S) when the STANDARDIZED REGRESSION COEFFICIENT of another predictor P (β_P) is greater than its correspondent VALIDITY coefficient (r_{CP}), assuming the predictor P is scored in the direction so that it is positively related to the criterion. That is, $\beta_P > r_{CP}$, which can further be expressed as

$$\frac{(r_{CP} - r_{CS}r_{PS})}{1 - r_{PS}^2} - r_{CP} > 0,$$

or $1 - \frac{r_{PS}}{k} > 1 - r_{PS}^2$ when $k = \frac{r_{CP}}{r_{CS}}$. The latter inequality suggests that the suppression effect is determined by r_{PS} and the ratio of two validity coefficients ($\frac{r_{CP}}{r_{CS}}$).

There are three types of suppression effect discussed in the literature: classic suppression, negative suppression, and reciprocal suppression. Classic suppression is characterized by a null relationship between the suppressor and the criterion (i.e., $r_{CS} = 0$), as shown in Table 1. Negative suppression occurs when the suppressor has a negative REGRESSION COEFFICIENT (i.e., -0.07 , shown in Table 2), although it is positively related to the criterion (i.e., 0.15). Reciprocal suppression occurs when the predictor and the suppressor are

Table 1 Example of the Classic Suppression

	Validity Coefficient	Standardized Regression Coefficient
Predictor (<i>P</i>)	0.20	0.27
Suppressor (<i>S</i>)	0.00	−0.13

NOTE: $r_{PS} = 0.5, n = 400$.

Table 2 Example of the Negative Suppression

	Validity Coefficient	Standardized Regression Coefficient
Predictor (<i>P</i>)	0.40	0.43
Suppressor (<i>S</i>)	0.15	−0.07

NOTE: $r_{PS} = 0.5, n = 400$.

Table 3 Example of the Reciprocal Suppression

	Validity Coefficient	Standardized Regression Coefficient
Predictor 1	0.50	0.65
Suppressor 2	0.20	−0.43

NOTE: $r_{PS} = -0.35, n = 400$.

positively related to the criterion, but are negatively related to each other. Reciprocal suppression is characterized when regression coefficients (in their absolute values) of the suppressor and the predictor are higher than their respective relationships with the criterion (see Table 3). In contrast to the two prior suppression situations, there are no clear characteristics in the reciprocal suppression associated with the suppressor, such as the null relationship between the suppressor and the criterion or the negative regression coefficient of the suppressor. Tzelgov and Henik (1991) suggested that reciprocal suppression is better defined in terms of “the effects of these variables on the regression weights of the variables they suppress” (p. 528).

The precondition of a suppression effect, $\beta_P > r_{CP}$, discussed so far can also be applied to cases with more than three variables as well as multivariate cases such as CANONICAL CORRELATION ANALYSIS or DISCRIMINANT ANALYSIS (see Tzelgov & Henik, 1991, for a detailed discussion). Under these complex circumstances, researchers are not able to identify which predictors are

suppressor(s) and which predictors are suppressed, although the existence of a suppression effect can be verified.

Contrary to conventional wisdom, Tzelgov and Henik (1991) provided convincing evidence that suggests suppression effects occur frequently. Because criterion-irrelevant variance in a predictor (or a set of predictors) is suppressed in the regression analysis, the suppression effect improves predictability. Should the suppression effect occur in cases with more than two EXOGENOUS VARIABLES, the theoretical mechanisms of these variables should be interpreted with extreme caution. Let’s use a two-predictor example described in Table 2 to illustrate this point. We choose two predictors as the example because the suppressor can be easily identified. Assume the job performance of programmers is the criterion, and programming skills and past experience with computers are the predictor and the suppressor, respectively. Although past experience *is* positively related to job performance, the negative regression weight suggests that more experience with computers is actually related to a decrease in job performance. Given the nature of the negative suppression effect, it is clear that past experience does *not* negatively influence job performance. It is the *measure* of past experience that suppresses criterion-irrelevant variance in the measure of programming skill, artificially boosting the regression coefficient for programming skill.

—Peter Y. Chen and Autumn D. Krauss

SURVEY

The social survey is a widely used method of collecting and analyzing social data for academic, government, and commercial research.

CHARACTERISTICS OF SURVEYS

Surveys are characterized by two essential elements (Marsh, 1982): the *form* of the data and the method of *analysis*.

Form of Data

Surveys produce a structured set of data that forms a variable-by-case grid. In the grid, rows typically represent CASES and columns represent VARIABLES. The cells contain information about a case's ATTRIBUTE on the relevant variable.

QUESTIONNAIRES are widely used in surveys because they ask the questions in the same way of each person and thus provide a simple and efficient way of constructing a structured data set. However, the cells in the data grid can, in principle, be filled using any number or combination of data collection methods such as interviews, observation, and data from written records (e.g., a personnel file).

Although the rows in the data grid frequently represent people, they can represent different UNITS OF ANALYSIS such as years, countries, or organizations. Where these types of units of analysis are used, the information in each column (variables) reflects information appropriate to that type of analysis unit (e.g., characteristics of a particular year, country, or organization).

Methods of Analysis

A second characteristic of surveys is the way in which data are analyzed. One function of survey analysis is to describe the characteristics of a set of cases. A variable-by-case grid in which the same type of information is collected about each case simplifies the task of description. However, survey researchers are typically also interested in EXPLANATION—in identifying causes. This is achieved by examining VARIATION in the DEPENDENT VARIABLE (presumed effect) and selecting an INDEPENDENT VARIABLE (presumed cause) that might be responsible for this variation. Analysis involves testing to see if variation in the dependent variable (e.g., income) is systematically linked to variation in the independent variable (e.g., education level). Although any such COVARIATION does not demonstrate CAUSAL RELATIONSHIPS, such covariation is a prerequisite for causal relationships.

Unlike EXPERIMENTAL research, in which variation between cases is created by the experimenter, social

surveys rely on existing variation among the cases. That is, survey analysis adopts a relatively *passive* approach to making causal inferences (Marsh, 1982, p. 6). A survey might address the question “Does premarital cohabitation increase or decrease the stability of subsequent marriage relationships?” It is not possible to adopt the experimental method in which people are RANDOMLY ASSIGNED to one of two conditions (premarital cohabitation and no premarital cohabitation) and then seeing which relationships last longer once the couples marry. The social survey adopts a passive approach and identifies couples who cohabited before marriage and those who did not and then compares their breakdown rates.

The problem in survey research is that any differences in marriage breakdown rates between the two groups could be due to differences between the two groups other than the differences in premarital cohabitation (e.g., age, religious background, ethnicity, race, marital history). Survey analysis attempts to control for other relevant differences between groups by statistically controlling or removing the influence of these variables using a range of multivariate analysis techniques (Rosenberg, 1968).

HISTORY

As a method of social research, social surveys have evolved from the primitive methods of 19th-century social reformers in Britain into a widespread and sophisticated research tool. The early surveys were conducted by British social reformers who studied the conditions of the poor affected by rapid industrialization. These surveys would be unrecognizable as social surveys today.

Modern surveys received considerable impetus from the needs for better knowledge about poverty, unemployment, and consumption patterns during the Great Depression of the 1930s and World War II. These massive social disruptions resulted in the establishment of major government surveys in Britain and the United States (e.g., the postwar Social Survey in Britain, Labour Force Surveys) and the establishment of survey research institutions such as the Bureau of the Census and National Center for Health Statistics in the United States. During World War II, the Research Branch of the U.S. Army recruited researchers such as Stouffer, Merton, Lazarsfeld, Likert, and Guttman, who became famous icons of survey research and became great innovators in the area

of survey analysis. After the war, these men established the groundbreaking university-based survey research centers that developed the methods of surveys and oversaw their increasing use in commercial and political research.

Developments in sampling methodology were crucial to the acceptance of survey research. In the early part of the 20th century, statisticians were refining sampling theory, but these developments had little impact on survey practice until the famous failures in predicting the winners of presidential elections in 1936 and 1948. The failure of NON-PROBABILITY SAMPLING led to the widespread acceptance of PROBABILITY SAMPLING methods from the 1950s onward.

The technology of social surveys has undergone substantial changes. Although structured, face-to-face interviews have been the preferred method of collecting survey information, declining response rates, expense, and safety considerations have encouraged the development of alternative data collection methods. Computerization and widespread telephone coverage have seen the widespread use of Computerized Assisted Telephone Interviews (CATI); the development of Computerized Assisted Personal Interviews (CAPI); and, more recently, Internet-based survey administration methods.

EVALUATION OF SURVEYS

Although surveys are widely accepted as a means of collecting descriptive, factual information about populations, they have faced criticisms as a means of learning about social phenomena and arriving at explanations of social processes and patterns.

Among the more important criticisms at this level are the following:

- The methods of collecting survey data are subject to considerable error stemming from sampling problems and flawed data collection instruments and methods.
- By collecting information about cases in the form of discrete variables, surveys fragment the “wholeness” of individual cases, fail to capture the meaning of attitudes and behavior for the individuals involved, and promote an atomistic way of understanding society—as a collection of discrete cases (Blumer, 1956).
- Social surveys rely on a positivist understanding of social reality, and because POSITIVISM is out of favor, surveys are condemned by association.

- The absence of experimental control and a time dimension in cross-sectional surveys means that survey research cannot adequately establish causal sequence and causal mechanisms.

Although all of these criticisms can be accurately applied to particular surveys, it is debatable whether these shortcomings are an inherent part of the survey method. Sustained research has been undertaken on ways of minimizing the sources of survey error (Groves, 1989). Marsh (1982) has argued that the criticisms in general are simply criticisms of poor surveys and argues that survey research is capable of providing an understanding of society that is adequate at the levels of both cause and meaning.

SYMBOLIC INTERACTIONISM

Symbolic interactionism is a major humanistic research tradition that highlights the need for an intimate familiarity with the empirical world. Drawing upon PRAGMATISM, and having affinities with POST-MODERNISM, it shuns abstract and totalizing truths in favor of local, grounded, everyday observations. The term was coined by Herbert Blumer in 1937 and brings a major commitment to QUALITATIVE RESEARCH. It

is closely allied to George Herbert Mead's theory of the self and to the research tradition of the Chicago sociologists (especially Blumer, Park, and Hughes). Commentators have suggested a number of stages in its development, ranging from the gradual establishment of the canon between 1890 and the later 1930s on through other phases to a more recent one of diversity and new theory that has strong affinities to postmodern inquiry.

Most symbolic interactionist sociologies, their differences notwithstanding, are infused with three interweaving themes, each with methodological implications. The first suggests that what marks human beings off from all other animals is their elaborate symbol-producing capacity, which enables them to produce histories, stories, cultures, and intricate webs of communication. It is these that interactionists investigate; and because these meanings are never fixed and immutable but always shifting, emergent, and ambiguous, conventional research tools of interviews or questionnaires may not be the most appropriate way of study. Rather, an intensive engagement with the lived empirical world is called for.

This points to a second theme: that of change, flux, emergence, and process. Lives, situations, even societies are always and everywhere evolving, adjusting, becoming. This constant process makes interactionists focus on research strategies to gain access to acquiring a sense of self, of developing a biography, of adjusting to others, of organizing a sense of time, of negotiating order, of constructing civilizations. It is a very active view of the social world in which human beings are constantly going about their business, piecing together joint lines of activity and constituting society through these interactions.

This suggests a third major theme: interaction. The focus of all interactionist work is with neither the individual nor the society per se; rather, its concern is with the joint acts through which lives are organized and societies assembled. It is concerned with "collective behavior." Its most basic concept is that the self implies that the idea of "the other" is always present in a life: We can never be alone with a "self." But all of its core ideas and concepts highlight this social other, which always impinges upon the individual: The very notion of "the individual," indeed, is constructed through the other. At root, interactionism is concerned with "how people do things together" (Becker, 1986).

Unlike many other social theories, which can soar to the theoretical heavens, symbolic interactionists stay

grounded on earth. Interactionist theory can guide the study of anything and everything social, although what will be discovered is always a matter of empirical investigation. But in principle, interactionists may inspect and explore any aspect of the social world.

Some strands of interactionism (often identified as the Iowa school and linked to measurement such as the Twenty Statements Test) have tried to make the theory more rigorously operational. Others claim it to be a different kind of science (such as Anselm Strauss and the GROUNDED THEORY methodology) and seek to make it more rigorous while sustaining its distinctive commitments. Still others (often associated with Norman Denzin and postmodernism) often see the theory as needing to take a much more political and critical stand.

SYMMETRIC MEASURES

Symmetric measures of ASSOCIATION describe the relationship between two variables *X* and *Y* without differentiating if either variable is an antecedent (or independent variable) or a consequent (or dependent variable). Examples of symmetric measures include PEARSON CORRELATION COEFFICIENT, SPEARMAN CORRELATION, Goodman and Kruskal's GAMMA COEFFICIENT, and point biserial correlation coefficient, in addition to the five measures to be presented below.

Table 1 Distributions of Gender (X) and Successfulness Records (Y)*Exhibit A*

	Failure ($Y = 0$)	Success ($Y = 1$)	Totals
Female ($X = 1$)	$20 = a$	$5 = b$	$25 = (a + b)$
Male ($X = 0$)	$10 = c$	$15 = d$	$25 = (c + d)$
Totals	$30 = (a + c)$	$20 = (b + d)$	$50 = a + b + c + d$

$$\phi = \frac{bc - ad}{\sqrt{(a + c)(b + d)(a + b)(c + d)}} = \frac{5 \times 10 - 20 \times 15}{\sqrt{30 \times 20 \times 25 \times 25}} = -.41$$

Exhibit B

X	Y	X	Y	X	Y	X	Y	X	Y	X	Y	X	Y	X	Y	X	Y	X	Y
1	1	1	0	1	0	1	0	1	0	0	1	0	1	0	1	0	0	0	0
1	1	1	0	1	0	1	0	1	0	0	1	0	1	0	1	0	0	0	0
1	1	1	0	1	0	1	0	1	0	0	1	0	1	0	1	0	0	0	0
1	1	1	0	1	0	1	0	1	0	0	1	0	1	0	1	0	0	0	0
1	1	1	0	1	0	1	0	1	0	0	1	0	1	0	1	0	0	0	0

$$\sum XY = 5, \sum X = 25, \sum X^2 = 25, \sum Y = 20, \sum Y^2 = 20$$

$$\phi = \frac{\sum XY - \frac{\sum X \sum Y}{n}}{\sqrt{\left(\sum X^2 - \frac{(\sum X)^2}{n}\right) \left(\sum Y^2 - \frac{(\sum Y)^2}{n}\right)}} = \frac{5 - \frac{25 \times 20}{50}}{\sqrt{25 - \frac{25^2}{50}} \sqrt{20 - \frac{20^2}{50}}} = -.41$$

NOTE: $X = 1$ (female), $X = 0$ (male); $Y = 1$ (success), $Y = 0$ (failure).

PHI COEFFICIENT

Phi coefficient (ϕ) is a special case of the Pearson correlation coefficient. When both variables, X and Y , are naturally dichotomous (e.g., male/female, success/failure, survival/death), the Pearson correlation is conventionally labeled as the phi coefficient. Because of its direct relationship with the Pearson correlation coefficient, the null hypothesis test and computation formula for the Pearson correlation coefficient can be applied to the phi coefficient.

Given the dichotomous nature of both variables (e.g., gender and successfulness), the distribution of gender and successfulness can be arranged in a table with four cells, often referred to as a CONTINGENCY TABLE, as shown in Exhibit A of Table 1. As seen, there are 20 successful females, 5 females who fail, 10 successful males, and 15 males who fail. Based on a simplified Pearson correlation formula,

$$\phi = \frac{bc - ad}{\sqrt{(a + c)(b + d)(a + b)(c + d)}}$$

[assuming $(a + c)(b + d)(a + b)(c + d) \neq 0$], the correlation between gender (X) and successfulness (Y)

is $-.41$, if females are CODED as 1 and males are coded as 0 for variable X , and success is coded as 1 and failure is coded as 0 for variable Y . Alphabetical letters a , b , c , and d represent the frequencies in each cell of the contingency table. We can also calculate the phi coefficient based on the conventional Pearson correlation formula. As demonstrated in Exhibit B of Table 1, the correlation between gender and successfulness is $-.41$. This negative correlation suggests that the higher the “gender” (from 0 to 1), the lower the “successfulness” (from 1 to 0). In other words, fewer females succeed than do males.

TETRACHORIC CORRELATION

If the phi coefficient is calculated based on two artificially dichotomized variables, actually CONTINUOUS VARIABLES with bivariate NORMAL DISTRIBUTIONS, the phi coefficient will underestimate the relationship between the variables. To estimate what the actual relationship would be if both variables were not artificially dichotomized, we could apply the tetrachoric correlation formula. For example, two variables, sleep (X) and

Table 2 Distributions of Sleep (X) and School Performance (Y)

	Poor Performance ($Y = 0$)	Good Performance ($Y = 1$)	Totals
Long Sleep ($X = 1$)	60 = a	40 = b	100 = ($a + b$)
Short Sleep ($X = 0$)	40 = c	60 = d	100 = ($c + d$)
Totals	100 = ($a + c$)	100 = ($b + d$)	200 = $a + b + c + d$

school performance (Y), are artificially dichotomized so that sleep is classified as either short sleep (if a person sleeps less than 7 hours) or long sleep (if a person sleeps equal to or more than 7 hours), and school performance is classified as either poor (if a grade point average is lower than 2.5) or good (if a grade point average is equal to or greater than 2.5). The frequencies for these two variables are summarized in the contingency table depicted in Table 2.

The tetrachoric correlation formula is defined as

$$r_{\text{tet}} = \frac{bc - ad}{\lambda_X \lambda_Y n^2},$$

where n is the total SAMPLE size, λ_X is the ordinate of the standardized normal distribution at

$$\frac{a + b}{a + b + c + d}$$

(i.e., proportion of subjects obtaining 1 for variable X), and λ_Y is the ordinate of the standardized normal distribution at

$$\frac{b + d}{a + b + c + d}$$

(i.e., proportion of subjects obtaining 1 for variable Y). Based on the data in Table 2, the tetrachoric correlation is computed as

$$r_{\text{tet}} = \frac{40 \times 40 - 60 \times 60}{.398942 \times .398942 \times 200^2} = -.31.$$

When compared to r_{tet} , ϕ based on the same data is much smaller ($\phi = -.20$). It should be noted that r_{tet} is an appropriate estimate of a relationship only for sample sizes greater than 400.

In the next two sections, we will describe two related measures of association, the contingency coefficient and Cramér's V . Both measures do not require any assumptions pertaining to the nature of the variables (e.g., normal vs. SKEWED, continuous vs. DISCRETE, ordered vs. unordered). Despite this advantage, any

pair of contingency coefficients or Cramér's V coefficients are not comparable unless the values of $\min(r, c)$ in both contingency tables are the same, where $\min(r, c)$ refers to the smallest number of rows (r) or columns (c) in a contingency table.

CONTINGENCY COEFFICIENT

We often conduct the CHI-SQUARE TEST (χ^2) to examine if there is an association between two categorical variables, which are presented in the form of a contingency table. For instance, a car dealer examines whether there is an association between color preference (e.g., white, black, gold, blue) and buyer ethnicity (e.g., Caucasian, Hispanic, African American) according to her customer database. Although she can apply the χ^2 test to see if any association between these two variables exists, the χ^2 value does not provide information about the magnitude of the relationship because two different χ^2 values may suggest the same magnitude of association. To address this limitation, the contingency coefficient, C , has long been applied, where

$$C = \sqrt{\frac{\chi^2}{n + \chi^2}},$$

and n is the total observed frequencies in the contingency table. By carefully examining the formula, it is clear that the contingency coefficient cannot approach unity even if there is a perfect association. Assuming there is a perfect association, the coefficient is equal to

$$\sqrt{\frac{c - 1}{c}}$$

if the contingency table has the same number of columns (c) and rows (r).

CRAMÉR'S V

Cramér's V was developed to resolve the limitation that the contingency coefficient cannot reach unity.

Conceptually, Cramér's V coefficient,

$$V = \sqrt{\frac{\chi^2}{n \times [\min(r, c) - 1]}}$$

is viewed as a ratio of an observed statistic to its maximum statistic. Therefore, the coefficient can range from 0 to 1. The null hypothesis test pertaining to both Cramér's V coefficient and the contingency coefficient can be conducted based on the χ^2 test of independence, with the DEGREES OF FREEDOM equal to $(r - 1)(c - 1)$.

KENDALL'S TAU

A rival of the Spearman correlation coefficient, Kendall's tau (τ) coefficient assesses the relationship between two ordinal variables, X and Y , based on n cases. Conceptually, it assesses the proportion of discrepancy between numbers of concordance and discordance expressed by

$$\tau = \frac{P - Q}{\frac{n(n-1)}{2}}.$$

P is the number of concordance, and Q is the number of discordance. (X_i, Y_i) from case i and (X_j, Y_j) from case j are considered to be concordant if $Y_i < Y_j$ when $X_i < X_j$, or if $Y_i > Y_j$ when $X_i > X_j$, or if $(X_i - X_j)(Y_i - Y_j) > 0$. Similarly, (X_i, Y_i) and (X_j, Y_j) are viewed to be discordant if $Y_i < Y_j$ when $X_i > X_j$, or if $Y_i > Y_j$ when $X_i < X_j$, or if $(X_i - X_j)(Y_i - Y_j) < 0$. Kendall's τ coefficient can range from -1 when $P = 0$ to 1 when $Q = 0$. Where there are tied ranks within variable X or variable Y , the maximum absolute value of Kendall's τ coefficient will be less than 1. Under this circumstance, researchers can employ either Kendall's τ_b coefficient or Stuart's τ_c coefficient. Both indexes differ in terms of how tied ranks are treated. Examples of applying these three coefficients are presented in Chen and Popovich (2002).

The NULL HYPOTHESIS test of $\tau = 0$ can be conducted by a z -test,

$$z = \frac{\tau}{\frac{\sqrt{2(2n+5)}}{3\sqrt{n(n-1)}}},$$

if the sample size is greater than 10. In contrast, a t -test shall be performed to examine the null hypothesis for both τ_b and τ_c (cf. Kendall & Gibbons, 1990).

SYMMETRY

Symmetry is a general property referring to the shape of a DISTRIBUTION, or to a COEFFICIENT that makes no distinction between the INDEPENDENT and DEPENDENT VARIABLE. A NORMAL DISTRIBUTION is symmetric, being bell-shaped with an equal number of cases scoring above and below the mean. A symmetric distribution is not SKEWED to the right or left. A coefficient is symmetric if, in its calculation, it is not necessary to declare variables independent or dependent. The PEARSON CORRELATION COEFFICIENT is symmetric, in that when estimated for two variables, Q and Z , the resulting value will be exactly the same value, regardless of whether Q is considered independent and Z dependent, or vice versa. In contrast, the coefficient LAMBDA is ASYMMETRIC, in that its value changes depending on which of the two variables is considered independent. Finally, it should be noted that symmetry is sometimes used to refer to the shape of a social structure, as in "network symmetry."

—Michael S. Lewis-Beck

SYNCHRONIC

Synchronic features describe phenomena at one point in time, implying the researcher employs a cross-sectional, snapshot, or static perspective (cf. DIACHRONIC).

—Tim Futing Liao

SYSTEMATIC ERROR

Systematic error is the consistent over- or underestimation of a PARAMETER. When the effects of systematic

Figure 1 Random Error

error are unaccounted for or ignored, analysts will draw incorrect conclusions from their research.

Analysts distinguish systematic errors from RANDOM ERRORS in the following way (see Walker & Lev, 1953): Suppose multiple measurements of a characteristic with a true value μ are taken. Some measurements generate estimates that are too large, whereas others are too small. If the instrument is unbiased, however, the positive and negative errors will cancel each other out, and estimates will be correct on average, centered at μ (see Figure 1).

Alternatively, a faulty instrument, for example, produces systematic error by reporting measurements that are, on average, larger (or smaller) than μ (see Figure 2).

Figure 2 Systematic Error

Repeated measurements are not centered at μ , but at the overestimated $\hat{\mu}$. Analysts should note that systematic error may affect all (as seen in Figure 2) or some proportion of measurements taken, or may affect different subsets of observations to different extents (Nunnally & Bernstein, 1994). In each of these cases of systematic error, a researcher's measurements are misleading: Whereas random error affects the precision of the estimate, systematic error biases the parameter estimate itself.

To illustrate, consider the following example: In democracies, a population's party preferences are measured through elections. Figure 1 reports the distribution of preferences in a two-party system: The horizontal axis indicates the strength of identification with a particular party ("Right"), and the vertical axis reports the number of citizens at a particular identification level. μ reports the true proportion of citizens who prefer the other party, "Left" to Right. However, elections are imperfect instruments for the measurement of a population's preferences. Suppose that voters who prefer Left are less likely to vote than those who prefer Right. In this case, the distribution of voters resembles that depicted by the solid line in Figure 2, which is centered at $\hat{\mu}$ (see Franzese, 2002) rather than the dotted line centered at μ . Conclusions about the distribution of preferences in a population based on this election result are likely to overestimate the popularity of Right.

This example suggests one type of systematic error, SELECTION BIAS. The selection of observations (voters rather than citizens) results in the miscalculation of support for Right within the population. However, several other types of systematic error may occur in social science research. Measurement error results when faulty instruments are used; the randomization of the order of response categories in survey research, for example, is an attempt to limit measurement error in survey response, because participants' answers have been shown to depend on the order in which response categories are presented (e.g., Wiseman, Moriarty, & Schafer, 1975–1976). CONFOUNDING error, another type of systematic error, occurs when an estimate of the relationship between two variables of interest is biased by the exclusion of a third, perhaps unobserved variable (or "confounder"). If, for example, Right party supporters are, on average, older than those who identify with the Left Party, there may appear to be a relationship between age and support for the

government policy. However, when the party identification is considered (see Figure 3), it becomes clear that party affiliation, regardless of age, is associated with attitudes toward the government policy.

Figure 3 Types of Systematic Error: Confounding Error

Therefore, analysts are well advised to take these and other sources of systematic error into account when constructing their models, or to anticipate the effects of systematic error when drawing their conclusions.

SYSTEMATIC OBSERVATION. See STRUCTURED OBSERVATION

SYSTEMATIC REVIEW

Systematic review describes a specific methodology for conducting reviews of literature. This methodology prescribes explicit, reproducible, and transparent processes for collating the best available evidence in answer to specific questions. In particular, it requires the use of robust techniques for searching for and identifying primary studies, appraising the quality of these studies, selecting the studies to be included in the review, extracting the data from the studies, and synthesizing the findings narratively and/or through pooling suitable quantitative data in META-ANALYSIS. Systematic review has developed in response to the perceived problems of traditional “narrative” reviews, where haphazard and idiosyncratic techniques, such as nonsystematic methods of literature identification and informal summary, can introduce bias. In health care, these problems had led to delayed introduction of effective treatments and continuation of ineffective treatments. Increasingly, systematic review extends beyond evaluation of interventions to embrace a diversity of RESEARCH QUESTIONS.

Systematic review has benefited from the development of electronic databases, allowing for more extensive and precise searching for candidate articles. Importantly, systematic reviews may, to reduce the risk of publication biases, also seek unpublished studies.

Systematic reviews critically appraise the quality of the relevant primary research, sometimes facilitated by checklists and scoring systems. RANDOMIZED CONTROL TRIALS (RCTs) are often seen as the “gold standard” of study design for evaluating interventions and are frequently found at the top of “hierarchies of evidence,” which grade study designs according to the RELIABILITY of the evidence they are likely to produce. However, conducting RCTs may not always be possible for practical, ethical, or economic reasons; sometimes, it is more appropriate or necessary to use non-RCT evidence.

Once the studies to be included in the review have been selected, and relevant data extracted, some form of synthesis can be attempted. Meta-analysis refers to statistical methods for pooling quantitative results from different studies (Egger, Davey Smith, & Altman, 2001). Sometimes, meta-analysis is used as a synonym for systematic review, but generally, a meta-analysis will form only part of a systematic review, and many

systematic reviews do not include meta-analyses. The feasibility of extending meta-analysis to include qualitative evidence using Bayesian statistical methods has recently been investigated. More usually, qualitative evidence, and quantitative evidence not meta-analyzed, are summarized narratively.

Since its introduction in the 1980s, systematic review has become central to the evidence-based practice movement in the health sciences. It is the core activity of the Cochrane Collaboration, an international network of groups producing systematic reviews of health interventions. The more recently established Campbell Collaboration will conduct systematic reviews in areas of social, behavioral, educational, and criminological intervention.

Well-conducted systematic reviews have already yielded significant benefits. The methodology has had only a short time to develop, and it will gain from further development and refinement. The frequent exclusion from some systematic reviews of some relevant data sources (e.g., from observational and qualitative studies) has been criticized (Dixon-Woods, Fitzpatrick, & Roberts, 2001). Recent guidance on the conduct of systematic reviews (NHS Centre for Reviews and Dissemination, 2001) has recognized these problems, and methods are now rapidly evolving to extend the science of systematic review to incorporate more diverse forms of evidence.

SYSTEMATIC SAMPLING

Systematic sampling involves selecting units at a fixed interval. There are two common applications. The

first is where there exists a list of units in the population of interest that can be used as a SAMPLING FRAME. Then, the procedure is to select every A th on the list. The second is where no list exists, but sampling of a flow is to be carried out in the field. (Examples of flows include visitors to a museum, passengers arriving at a station, and vehicles crossing a border.) Then, the procedure is to select every A th unit passing a specified point. This is conceptually equivalent to creating a list of units in the order that they pass the point and then SAMPLING systematically from the list, so the principles of systematic sampling can be illustrated by considering only list sampling.

The first step in systematic sampling is to calculate the sampling interval, $A = \frac{N}{n}$. For example, to select a sample of $n = 100$ from a list of $N = 1,512$ units, then $A = 15.12$. The second step is to generate a random start. This will determine which is the first unit on the list to be sampled. In fact, it will determine the entire sample, because the remaining selections are obtained by repeatedly adding the fixed interval; no further random mechanism is involved. The random start should be a number between 1 and $1 + A$. Step 3 is to successively add A to the random start. Thus, if the random start is 4.86, the following numbers will be obtained: 4.86, 19.98, 35.10, 50.22, . . . , 1501.74. The final step is to ignore the decimal places—the sampled units are the 4th, 19th, 35th, 50th, . . . 1501st on the list. This procedure will result in the selection of exactly n units. In the case of flow sampling, N is unknown, so A is usually chosen on practical grounds.

A common motivation for using systematic sampling is practical simplicity. The case of flow sampling is a good example. In many situations, there is no other way to select a random sample from a flow, because no lists exist and it is not possible to create such a list in order to sample subsequently from the list in some other way. Practical considerations also apply in other situations. For example, consider sampling from a set of card files arranged in a series of filing cabinets. Systematic sampling avoids the need to remove the cards from the cabinets and re-sort them, or to number all the cards. It is necessary only to count through them.

If the units are ordered in a meaningful way, systematic sampling has the (typically beneficial) effect of achieving implicit stratification (see STRATIFIED SAMPLE). This is often perceived as an advantage of systematic sampling over SIMPLE RANDOM SAMPLING.

Many surveys employ systematic sampling within explicit strata. Again, the same argument applies to systematic flow sampling. If a survey is sampling visitors to a museum and there is a tendency for visitors with different characteristics to be represented in different proportions at different times of day, then systematic sampling over the course of a whole day should result in improved precision of estimation compared with a simple random sample of the same size of that day's visitors.

TAU. See SYMMETRIC MEASURES

TAXONOMY

Taxonomy is a term that is particularly associated with biology and refers to classification. Taxonomies (e.g., types of society, political systems) are often controversial in terms of issues such as whether the classification categories are innate or fabricated by the taxonomist.

—Alan Bryman

TCHEBECHEV'S INEQUALITY

Sometimes spelled Chebyshev's Inequality, the inequality allows for the derivation of probability bounds if only the MEAN and VARIANCE of a RANDOM VARIABLE are known. Its primary importance is in terms of its use as a tool for deriving more theoretical results (e.g., the weak LAW OF LARGE NUMBERS).

Mathematically, for random variable X with finite mean μ and variance σ^2 , then for any $y > 0$, the (two-sided) Tchebechev's Inequality is given by

$$P\{|X - \mu| \geq y\} \leq \frac{\sigma^2}{y^2}.$$

Intuitively, Tchebechev's Inequality indicates that if the variance σ^2 of a random variable is small, then X will be very close to μ .

To illustrate how Tchebechev's Inequality can be used to compute population bounds when the distribution of the random variable is unknown, consider a hypothetical case. If the average grade in a class is 75 with a variance of 20, the upper bound on the probability that a randomly selected student will have a grade below 65 or above 85 is

$$P\{|X - 75| \geq 10\} \leq \frac{20}{100} = 0.20.$$

Because no information about the distribution is used to calculate the bound, the upper bound may not be particularly accurate. For example, if we knew that the distribution of class grades was the NORMAL DISTRIBUTION, the actual probability of the above event is approximately 0.026—quite far from the bound of 0.20 provided by Tchebechev's Inequality.

Defining $y = t\sigma$ permits Tchebechev's Inequality to bound the probability that X is no more than t standard deviations away from its mean, μ :

$$P\{|X - \mu| \geq t\sigma\} \leq \frac{1}{t^2}.$$

Continuing the above example, the upper bound on the probability that the grade of a randomly selected student will be more than two standard deviations away from the class mean is less than or equal to 0.25.

It is also possible to derive the one-sided inequality for any $y > 0$:

$$P\{X \geq y\} \leq \frac{\sigma^2}{\sigma^2 + y^2}.$$

Although the ability to compute probability bounds for a random variable without knowing its distribution

is useful, Tchebechev's Inequality is most important as a tool for deriving a weak law of large numbers and for proving that convergence in mean square implies convergence in probability.

T-DISTRIBUTION

The *t*-distribution is the DISTRIBUTION for the *t*-variable. The British statistician and brewmaster William Gosset introduced the *t*-variable around 1900. He found the distribution by what today we would call SIMULATION. He made a histogram of 750 quantities he had computed and observed that the HISTOGRAM deviated some from a NORMAL DISTRIBUTION. He called the new distribution the *t*-distribution and the variable the *t*-variable. Later, Sir Ronald A. Fisher derived the mathematical formula for the distribution. A *t*-test uses the statistical *t*-variable to find the *P* VALUE for a statistical test.

The *t*-variable is a family of variables, each with its own distribution. All of the distributions are symmetric and bell shaped, but they are more spread out than the normal distribution. The variables and their distributions are numbered 1, 2, 3, and so on. This number is known as the DEGREES OF FREEDOM for the variable. The larger the degrees of freedom, the more the distribution resembles the normal distribution.

A *t*-test can be used for many different null hypotheses. The most common *t*-tests are for a single MEAN, the difference between two means, and a REGRESSION COEFFICIENT. For all these cases, the test statistic is a linear combination of the observations on the DEPENDENT VARIABLE.

t-test for a single population mean. The NULL HYPOTHESIS states $H_0: \mu = \mu_0$. The population mean is denoted μ , and the hypothesis states that the

population mean is equal to a numerical value μ_0 . The test statistic *t* is computed according to the following formula:

$$t = \frac{\bar{y} - \mu_0}{s/\sqrt{n}}.$$

Here, $\bar{y}$ is the SAMPLE mean of the variable, *s* is the sample STANDARD DEVIATION of the variable, and *n* is the number of observations in the sample. The value of the *t*-variable computed this way is for the *t*-variable with *n* – 1 degrees of freedom. Using *t* and the degrees of freedom, we can then find the corresponding *P* VALUE from tables of the *t*-distribution or from statistical software.

When the sample is small, say, less than 30 observations, the formula for the test statistic works best when the variable *Y* follows a normal distribution. For large samples, this requirement is not necessary.

t-test for the difference between two population means μ_1 and μ_2 . The null hypothesis states $H_0: \mu_1 - \mu_2 = 0$ (or any other numerical value).

The corresponding *t*-value has $n_1 + n_2 - 2$ degrees of freedom. The test works for any numerical value of the difference between the two means, not just 0. The formula for *t* can be found in any statistics textbook, and it is built into almost all statistical computer packages.

The test works best when the variable follows a normal distribution in each population and when the VARIANCES in the two distributions are equal. When the sample sizes are larger than, say, 30, these requirements are less important.

t-test for a regression coefficient β . In a regression study of an independent variable *X* and a dependent variable *Y*, we can test $H_0: \beta = 0$. The corresponding *t*-value has *n* – 2 degrees of freedom. The test works best when the *Y* values are distributed normally around the regression line.

TEAM RESEARCH

Team research refers generally to research in which two or more people collaborate sufficiently to share authorship of findings disseminated to others, most frequently through scholarly publication. It may involve one or a stream of projects. It is distinguished from single-author research, including research authored by one person but conducted with the assistance of others, in that responsibility for a complete research project, from initial conceptualization through dissemination of findings, is shared to some extent by those collaborating on the research.

Team research may take a wide variety of forms. The most standard involves two or more scholars working together on a research project and publishing one or more discrete papers on it. The scholars may be from the same institution and academic discipline or different institutions and disciplines; they may be faculty, students, or scholar-practitioners; they may be in the same location or multiple locations; and they may have similar or differing conceptual and methodological strengths.

A more complex form includes two or more scholars working together as a team on a stream of research over an extended period of time. They may view themselves as a team even if some of the individual studies of the research stream are published individually or with others who are not part of the team.

Another more complex form involves practitioner members of a setting sharing responsibility with one or more scholars for studying the setting and disseminating the research findings both externally and internally. This may take the form of ACTION RESEARCH, in which addressing a particular practical concern in the setting and scholarly dissemination of findings from addressing it are both aims.

There are both product and social motivations for conducting team research. Product motivations include the belief that the contributions of multiple authors, often with different types of knowledge, are necessary to address particular research questions adequately and creatively. Social motivations include desires to work with friends and to help develop younger scholars by including them in research. A motivation for action research is the ability to make both practical and scholarly contributions related to a particular problem in a setting.

HISTORICAL DEVELOPMENT

Research collaboration between scholars, particularly in the hard sciences and medicine, appears to have developed initially in France toward the end of the 18th century. Such collaboration grew substantially after World War I. Team research in the social sciences, in both its scholarly and action research forms, has been recognized as a distinguishable form of research at least since the 1940s, although it is less frequent than team research in the hard sciences (Bayer & Smart, 1991).

CHARACTERISTICS AND SKILLS NEEDED

Team research evokes all the dynamics of any group, including developing roles, leadership, norms, cohesion, and a balance between task and social dimensions (Del Monte, 2000). For team research to succeed, several skills and activities on the part of team members are required. In particular, this type of research involves considerable social competence, especially in dealing with potential conflicts and negotiating agreements.

There are several aspects about which it is crucial for team members to reach agreement. These include the hoped-for outcomes of the research, how the work and responsibility for the individual study and/or stream of research will be divided, the research questions to be explored, how to gather and analyze the data, who owns the data that are gathered, how to interpret the meanings of the results, confidentiality and decisions regarding sharing information with research participants, the means by which outcomes of the research will be disseminated, and the order of authorship of publications that might result from the research. In action research, it is also necessary to reach agreement regarding the means by which both practical and scholarly purposes are to be pursued.

Reaching agreement on dimensions like these is particularly important and difficult when the research team includes members who operate out of different cultural values (e.g., practice vs. scholarship, qualitative vs. quantitative methodological emphases); differ in power, status, and knowledge about how to do the type of work that will be involved; and/or differ on which aims are primary for them. Moreover, communication regarding these issues and updated agreements will likely need to occur on an ongoing basis throughout the research endeavor. This is especially the case for research teams whose expectations of joint research extend beyond an individual project.

POTENTIAL BENEFITS

There are several potential benefits of team research. One is the advantage of multiple and differing viewpoints, which, other things being equal, typically lead to a more creative approach to the research. Another benefit is that researchers can address larger problems than would be the case if they were working independently. Yet another is that team approaches to research often result in improved studies. For example, in many fields, the more prestigious journals typically have a higher proportion of collaboratively authored papers than do other publications (Bayer & Smart, 1991). There also tends to be a positive relationship between coauthorship (as opposed to single authorship) and both acceptance and citation of articles. Furthermore, even though team research may be difficult, it may also be challenging and exciting, at least when its social dynamics are handled well.

POTENTIAL PROBLEMS

Although there are multiple potential benefits, there are also many potential problems that arise in team research. It is often necessary to resolve disagreements regarding the order of authorship or inclusion of authors, and, more generally, how to allocate credit fairly among different team members. Sometimes, there are concerns about social loafing on the part of some members of the research team who do not carry through on their responsibilities. In addition, especially when multiple disciplines or multiple cultures are present within the team, differences in values, experiences, norms, and communication styles among team members may all cause conflicts, some of which may not be resolvable in a collaborative way. All of these potential problems are exacerbated when there are power and status differentials among members of the research team. If these problems are not addressed satisfactorily, the expected benefits of team research will not be experienced.

EXAMPLES

Examples of team research in which two or more scholars work together are ubiquitous in virtually all social science fields. Kirkman, Rosen, Gibson, Tesluk, and McPherson (2003), along with others, illustrate a team carrying out an extended stream of research—in their case, on virtual teams. Bartunek and Louis (1996) present many examples of insider members in education, community settings, and work

organizations collaborating in research on the setting with external researchers. Such collaboration may include an action research component, but this is not necessary.

TELEPHONE SURVEY

Surveys by telephone continue to be the most frequently utilized technique of asking a standardized set of questions with the purpose of gathering information from POPULATIONS, large and small, for a variety of purposes on almost any topic in the United States and in many other countries. Academic, governmental, and commercial organizations implement telephone surveys routinely for marketing, policy, media, public opinion, value assessment, demographic background, impact assessment, and many other purposes. The telephone survey has replaced the face-to-face household survey as the most often implemented survey technique because of improved probability sampling techniques; enhanced coverage, with virtually every household having a telephone; tried and tested techniques of question wording and questionnaire construction; improved quality control over the data-gathering process; and advances in telephone technology. These improvements, coupled with the demand of the consumers of SURVEY research for almost immediate retrieval of results, the lower costs of telephone research, and declining response rates to face-to-face surveys, have led to the prominence of surveys by telephone.

ADVANTAGES

Several factors contribute to the popularity of surveys by telephone. First, the use of the telephone

is reinforced by social norms that “demand” a person answer a ringing telephone within 3 to 4 rings, and that the person calling (i.e., the interviewer) be the person to terminate a conversation. Second, telephone surveys are cheaper than those conducted face-to-face and cost about the same as mail surveys because of lower field and personnel costs. Third, the time it takes to complete a telephone survey and get the results to the researcher or sponsor is considerably less than for any other type of survey. In fact, “instant polls,” often used by political figures seeking a public’s response to a policy proposal, can produce results within 24 hours of the first call. Fourth, CONFIDENTIALITY of respondent identity and response is enhanced because the telephone interviewers know fewer respondent identifiers, usually only a telephone number, than do interviewers in other surveys. Fifth, the effects of interviewer characteristics on response are less than those for face-to-face interviews because there is only voice contact, and the race or age of either interviewer or respondent is not generally identifiable. Therefore, telephone responses are less susceptible to socially desirable response patterns because of these physical features. Sixth, telephone surveys, particularly with the establishment of telephone centers that operate computer-assisted telephone interviewing (CATI), provide the opportunity for quality control over the entire data-gathering process because supervisors can provide immediate feedback to interviewers. In addition, these facilities almost always have the capacity for monitoring the interview via a satellite computer terminal. Seventh, coverage is no longer a problem because virtually 100% of households have telephone access, and RANDOM-DIGIT DIALING (RDD) procedures make it possible to access a telephone number without depending on a SAMPLING FRAME that lists addresses or names. Established techniques for sampling within households, such as the last/first birthday or household enumeration procedures, make it possible to continue the probability selection of a respondent. Finally, it is possible to ask questions on almost any given topic, sensitive or not. Because the telephone is such a standard means of communication, and because most countries can be characterized as “interview societies” where the interview, often by telephone, is the universal mechanism of inquiry, respondents are used to providing information to others, even to those they do not know.

DISADVANTAGES

Although many factors promote the use of telephone surveys, there are also detracting elements. First, it is easier to hang up on a telephone conversation than it is to shut the door in someone’s face. Thus, refusal is easier, making response rates to telephone surveys slightly lower than those obtained in the face-to-face survey. Refusal conversion is possible, but this is time-consuming and expensive and may produce only a 15% to 20% success rate. Second, the length of a telephone interview is limited to about 20 to 25 minutes, whereas face-to-face interviews can often go much longer and thus enable the inquiry to go into greater depth and detail. Although it is possible to ask OPEN-ENDED QUESTIONS in the telephone survey, recording the responses and probing for more depth are more difficult. Thus, telephone survey questionnaires tend to rely on structured, CLOSED-ENDED QUESTIONS because they seem easier to answer via telephone than are open-end, unstructured items. Third, because the interviewer and respondent are not in physical presence, the telephone interviewer cannot observe physical surroundings or obtain nonverbal cues, but can depend only on voice quality. Nor can the telephone interviewer use visual aids, as is possible with the face-to-face interview. Fourth, developments in telephone technology have certainly made it easier to conduct surveys, but recent innovations have contributed to making this task more difficult. Almost all households have either an answering machine, call waiting, call identifier, or modem access to the household line, each of which presents an obstacle to reaching a respondent. Prospective respondents almost never return a call to interviewers in response to a message left on an answering machine or interrupt a telephone conversation to take a call from a survey organization. Callbacks in these circumstances add to total survey cost. Fifth, legitimate surveys by telephone are compromised by the public’s generally negative view of surveys or inquiries by telephone as the result of annoying telemarketing or sales pitches that come after the caller has used the idea of a survey to get a “foot in the door” to a household in order to sell a product. This is also called “sugging.” Push polls or political propagandizing disguised as legitimate polling, and “frugging,” or fundraising under the guise of surveys, also contribute to this climate, promoting routine refusal of any inquiry, including the most legitimate surveys.

SAMPLING

The development of the RDD sampling technique made it possible to access almost every household in a country or community that had a telephone, whether the number was listed or not in the local telephone directory. Because, in some communities, up to 40% of all household numbers were unlisted by choice or because the number had not yet been entered in the printed directory, it was necessary to find a procedure that overcame the unlisted problem. RDD depends on a listing of numbers in use by exchange. Thus, it is possible to know which exchanges (e.g., 735, 542) are in use in an area, as well as the range of four-digit numbers in use in each exchange. Only 10,000 numbers are possible in each exchange. Using a random-number procedure, the appropriate set of numbers can be generated and called. One problem with this technique is the inability to screen out commercial numbers or cell phone numbers, thus making it more difficult to reach an eligible household. Also, the fact that many households now have more than one phone makes the probability of the selection of these respondents greater than those with one phone. Finally, even though exchanges have a geographical distribution over a city or country, they cannot be matched to smaller housing developments or neighborhoods. Locating eligible households in smaller geographic areas makes sampling more difficult and expensive, even with the ability to purchase custom-designed samples from commercial sampling vendors.

CONCLUSION

Issues of question order, question wording, response patterns, establishment of rapport, question complexity, and coding are similar regardless of type of survey. There is considerable research on these and other issues to the point that tested techniques of questionnaire construction and question writing are in place for telephone surveys and serve to reduce, at least, variations in response due to these factors. Data quality for telephone surveys is on par with that of other types and even improved as the result of lessened "demand" factors attributable to the physical presence of the interviewer. As indicated above, quality control of the interview process, and ultimately of data quality, is improved with the use of CATI systems, where questionnaires are presented to interviewers in an automated and controlled sequence of questions, reducing the potential of interviewer error.

Pencil-and-paper versions of telephone interviewing have all but disappeared in favor of the use of CATI systems. Although the latter are expensive, they provide almost instant results, the enhanced ability to schedule callbacks on a random schedule, and the ability to control the distribution of the sampling pool. Telephone surveys are now being used as part of "mixed mode" research, where several data-gathering techniques are used in the same research project. This makes it possible to increase response rates and overall sample coverage. Conducting surveys is now big business in almost every country of the world, with surveys by telephone a prominent component of that enterprise.

TESTIMONIO

Testimonio is generally defined as a first-person narration of socially significant experiences in which the narrative voice is that of a typical or extraordinary witness or protagonist who metonymically represents others who have lived through similar situations and who have rarely given written expression to them. Testimonio is then the "literature of the nonliterary" involving both electronic reproduction, usually with the help of an interviewer/editor, and the creative reordering of historical events in a way that impresses as representative and "true" and that often projects toward social transformation. In the 1970s and 1980s, many testimonios appeared, especially throughout Latin America, including narratives of indigenous representatives and labor and guerrilla leaders. In

the 1990s, testimonios shifted toward representatives of nongovernmental organizations and broader social movements that favored human, women's, and gay rights, as well as ecological and antiglobal movements. *I, Rigoberta Menchú* became the most famous of many testimonios, and the recent attacks against this text have problematized testimonio as a viable expressive form.

Testimonio suggests testifying or bearing religious or legal witness, and the overall narrative unit is usually a life or a significant life experience. Many critics have seen the form as an expression of those marginalized by capitalist modernization. Testimonio was also seen as involving the intervention or mediation of a lettered intelligentsia. Elzbieta Sklodowska (1992) gave the most nuanced treatment of testimonio as a literary form, but John Beverley (1989; Beverley & Zimmerman, 1990) presented the most influential interpretation of testimonio's social dimensions. For Beverley and Zimmerman (1990), "Testimonio [was] usually a novella-length first person narrative recounted by the protagonist or witness to the events recounted" (p. 173). Furthermore, testimonio signaled an overall transformation in social and literary formations and even in transnational modes of production (p. 178).

Noting that testimonio-like texts had long been at the margin of literature, Beverley (1989) argued that testimonio was marked by its conflictive relation with established literary-aesthetic norms and with the institution of literature itself. Testimonio could be defined as "a nonfictional, popular-democratic form of epic narrative, since the narrative has a metonymic function which implies that any life so narrated can have a kind of representativity" evoking an implicit "polyphony of other possible voices, lives and experiences" (Beverley & Zimmerman, 1990, p. 175).

The presence of the "real," popular voice in testimonio is, in varying degrees, an illusory or indeterminate "reality effect" that can be readily challenged (cf. David Stoll's, 1999, effort to discredit Rigoberta Menchú and her book), but the effect's persistence helps to explain testimony's special force. A testimonial text simultaneously represents certain perspectives and questions supposed verities, but it is never "the truth."

Testimonio has declined in recent years, along with the social upheavals that produced the key examples. However, as an expression of gender and other identity-shaping differentials, testimonio on its own, and in its use in novels, poems, and plays, will long

remain part of Latin American and global literature as a discursive mode available to individuals related to subaltern sectors and social movements.

—Marc Zimmerman

TEST-RETEST RELIABILITY

Individual responses or observed scores on a measure tend to fluctuate because of temporary changes in respondents' states. Test-retest RELIABILITY provides an estimate of the stability (or instability) of the responses on the same measure over time. In other words, it assesses the amount of measurement ERRORS resulting from factors (e.g., maturation, memory, stressful events) that occur during a period of elapsed time. The procedure to ESTIMATE test-retest reliability is as follows. The same measure is administered to one group of participants at two different times with a certain amount of elapsed time between administrations. The two sets of scores on the measure are then correlated using the following formula:

$$r_{XX'} = \frac{\sum (X_i - \bar{X})(X'_i - \bar{X}')}{n s_X s_{X'}}$$

where X and X' represent the two administrations of the same measure, s_X and $s_{X'}$ are STANDARD DEVIATIONS of X and X' , and n is the number of respondents in the sample. This CORRELATION coefficient represents the estimate of test-retest reliability and is also referred to as the coefficient of stability.

Theoretically, a test-retest reliability estimate can range from 0 to 1, although it is not unlikely to observe negative values for measures prone to fluctuating responses. In general, there is no established minimum value that indicates an acceptable level of test-retest reliability. Additionally, the expected size of the test-retest estimate may depend upon the nature of the construct being assessed. For instance, it is unrealistic to expect high test-retest reliability for a measure that assesses transitory properties (e.g., mood). Therefore, test-retest reliability estimates tend to be higher for aptitude tests or personality measures, considered to be assessing more stable constructs, when compared to attitudinal measures or polls.

The test-retest approach is an appropriate reliability estimation technique when (a) little or no change in the characteristic being assessed is assumed to occur between the two administrations, and (b) the test material will not affect responses to subsequent presentations of the stimuli. Regarding the first circumstance, the amount of elapsed time between test administrations is an important but often neglected issue. The amount of time should be long enough to avoid any effects from memory or practice but should not be so long that the participant's level of the characteristic of interest may actually change. As a heuristic, the determination of time lapse between the two administrations should be guided by the construct's theory. According to the development of intelligence, adults' intelligence scores are not expected to change drastically between the ages of 20 and 25. High test-retest reliability (e.g., 0.80) with a 5-year time lapse provides stronger evidence of VALIDITY than the same test-retest reliability with a 2-week time lapse. On the other hand, a presumably reliable intelligence measure for infants may have very small test-retest reliability if the period of time lapse is longer than a year.

Regarding the second circumstance, research has indicated that a test-retest reliability estimate may be affected by psychological factors such as practice effects for cognitive tests or carry-over effects for attitudinal measures. For instance, people taking the same cognitive ability test may understand the problems better because of the second reading, or people may respond consistently to survey questions simply because they remember how they responded to the items previously. These BIASES could inflate the reliability estimate, as in the case where participants respond in an artificially consistent manner, but they could also result in a lower test-retest reliability

estimate, such as in the case where participants score better on a cognitive ability test the second time, causing less consistency between test scores.

TETRACHORIC CORRELATION. See SYMMETRIC MEASURES

TEXT

The term *text* is a beguilingly short word that has become extremely elastic in meaning. Historically, its initial associations were with written forms of communication, especially those from biblical and legal sources, carrying with them a sense of authority and authoritative meaning. This sense was carried over into the idea of an author considered as the sole basis of meaning in a text. Text-based criticism thus found its rationale in locating and commenting on the author's intended meaning. Such a conception of a text has been radically overhauled in several major ways. What is now questioned is not only whether an author's intended meaning is knowable, but also whether we can speak of a text's single, final, or "true" meaning. Readers are held to construe their own meanings from a text, and these are always context-dependent. At one extreme, this leads to the reductions of historicism and cultural RELATIVISM, but rejection of the narrow focus of authorship studies, and the notion of a text's univocal meaning, is well-founded. Texts are plural and variable in their meanings, both within and across time. Just as a text is constructed in terms of particular codes and conventions, so also is it interpreted and understood; hence, its inherent semantic instability. A text cannot mean just what we take it to mean, though, for we must always take our interpretative cue

from what is set forth on the page. Yet it is not just written or word-processed communication that is now in the frame, for the term *text* has been extended to such diverse cultural forms as television, film and photography, popular song and music, sport and fashion, advertisements, household appliances, and architecture. Exclusive attention to the textuality of such forms can lead to formalist and antirealist positions, as in certain branches of POSTSTRUCTURALISM, which hold that texts have no reference but to themselves and other texts, in an endless play of signification and intertextuality. It is more generally accepted that the relations between texts and their social, cultural, and historical contexts are mediated by the narratives, genres, and discourses in which they operate and in terms of which they derive their wider meanings. While all the major disciplines in the human and social sciences have now had to negotiate the many implications of this, the adequacy of interpretation and understanding based only—or primarily—on textual analysis has just as generally been questioned. Analyzing texts is indispensable in developing a broad understanding of what is given to us as we attend to different forms of communication—whether these reach us through page, screen, or speaker—but it cannot tell us everything that is involved in their production and consumption. Broad understanding requires other methods of study alongside textual analysis. The danger of a self-confined textual analysis lies in assuming that it can embrace all that contributes to a text's construction and interpretation, as if all of that can, indeed, be "read off" from the text alone. This raises a further danger. It is one thing to say that the way a text, in its extended sense, is structured and assembled mediates what it says of the world, but quite another to assert that the world is, always and everywhere, only constituted in texts and text-analogues. The danger is then that of textualizing the world. This means seeing the world exclusively in terms of the text, outside of which nothing exists. To the contrary—we make the world meaningful only within cultural texts, but their significance lies in the references they establish to the world that exists beyond them.

THEORETICAL SAMPLING

The relation between data and theory rests at the heart of empirical social science, and SAMPLING helps to define that relationship. RANDOM SAMPLING are used to generate DATA for purposes of verifying hypotheses derived from existing THEORY. In contrast, theoretical sampling, which is contained within the GROUNDED THEORY approach (Glaser & Strauss, 1967), is an analytical process of deciding what data to collect next and where those data should be found. It is a version of ANALYTIC INDUCTION in that an emphasis is placed on the analyst jointly collecting, CODING, and analyzing data for purposes of developing theory as it systematically emerges from data.

The central issue in this procedure centers on the theoretical purposes for collecting new data as well as deciding what kinds of data are needed for those purposes. This process goes hand in hand with the CONSTANT COMPARISON method, in which categories, situations, and analytical dimensions are continuously searched for during the research process. By combining theoretical sampling and constant comparison, theory that is tightly integrated and tied to its supporting data can be developed more efficiently.

Integration of a developing theory can be provided through several means, but emphasis is placed on two primary mechanisms. The first is selecting new data sites that specifically address provisional hypotheses grounded in data. Maines (1992) illustrates this process in his study of New York subway riders. Attempting to explain rider distributions, he first collected observational data from riders in subway cars, which led to a hypothesis suggesting that observational data should be collected from riders' waiting positions on subway platforms, which then led to a new hypothesis suggesting that observational data be collected on riders' routes of movement through the cars, which finally led to a hypothesis requiring interview data comparing riders who remained in the car they entered with those who walked to another car before taking a seat. At each stage of the research project, provisional theories were constructed that explained existing data, and qualities of those provisional theories suggested the kinds and sources of new data required to improve the explanatory capacity of the developing theory.

The second mechanism is CODING. Strauss (1987, Chap. 3) identifies three types of coding procedures that are linked to theory development. The first is *open coding*, in which data are explored for purposes of discovering categories and central themes. This process typically occurs early in the research process. The second, *axial coding*, focuses on the identification of core categories and their properties, and theorizing the conditions under which these properties (or dimensions) would occur as well as their relationships to other categories and their properties. The third procedure is *selective coding*, which entails the more theoretically purposeful specification of relationships among categories and subcategories.

Soulliere, Britt, and Maines (2001) demonstrate how combining theoretical sampling and coding for core categories is compatible with conceptual modeling. Focusing on the category of "Professionalism," they show how a concept-indicator model can be respecified on the basis of new data and presented as a concept-concept model. This modeling process is an explicit application of the grounded theory tenet of moving theory from concrete to more abstract and generic formulations.

—David R. Maines

THEORETICAL SATURATION

Theoretical saturation is the phase of qualitative data analysis in which the researcher has continued sampling and analyzing data until no new data appear and all concepts in the theory are well-developed. Concepts and linkages between the concepts that form the theory have been verified, and no additional data are needed. No aspects of the theory remain hypothetical. All of the conceptual boundaries are marked, and

allied concepts have been identified and delineated. NEGATIVE CASES must have been identified, verified, saturated, and incorporated into the theoretical scheme.

Underlying theoretical saturation is the notion of *theoretical sensitivity*. The main assumption of theoretical sensitivity is that data analysis is *data driven*. That is, categories cannot emerge until they "earn their way" into the theoretical scheme (Glaser, 2002). This means that some categories that are almost always included in a study, such as gender, cannot assume a place in the study until data analysis reveals that the constructs demand to be included. Once these constructs have appeared, sampling must continue until they are saturated.

The term *theoretical saturation* is used primarily in connection with GROUNDED THEORY, but may be applied to any qualitative research that has the end goal of developing a qualitatively derived theory. Qualitatively derived theory differs from theory used in QUALITATIVE RESEARCH—whereas theory in QUANTITATIVE RESEARCH is based on and derived from previous inquiry (and the proposed project is an extension of that work), theory in qualitative inquiry is developed systematically from data. Although the results remain a *theory* (in that it is a conceptual abstraction of those data), qualitatively derived theory differs from theory in quantitative inquiry in that it more closely resembles reality. Qualitatively derived theory is the product or outcome of inquiry, not a conceptual framework to be tested, as in quantitative inquiry. In qualitatively derived theory, concepts must be well developed and their linkages to other concepts clearly described (Morse, 1997). Criteria for evaluating the emerging theory are that it must be comprehensive, parsimonious, and complete; it must have grab; and it must be useful (Glaser, 1978).

An example of a theory that is developed using theoretical saturation is the classic monograph by Anselm Strauss and his colleagues (1984). In this grounded theory, they describe many aspects of individuals' experiences with chronic illness, including the trajectory of illness and hospitalization, the impact on the family, and the use of community services such as self-help groups. They write of the basic strategy, for instance, not as symptom control or staying alive, but as *normalizing*. In this research, the process of making their lives (and their families' lives) as normal as possible depends not only on the arrangements, but also on "how intrusive are the symptoms, the regimens, the knowledge that others have the disease and of its

fatal potential” (Strauss et al., 1984, p. 79). If these illness factors become intrusive, then people have to “work very hard at creating some semblance of normal life for themselves” (p. 79). The description of what Strauss et al. term “abnormalization and normalization of life” is a excellent illustration of the richness and the complexity of qualitatively derived theory that may be attained when the investigators have used the principles of theoretical sensitivity during data collection and analysis.

THEORY

There can be few terms in the social sciences whose usage is more diverse, and often vague, in meaning than “theory.” There are at least three different contrasts involved: with practice, with fact, and with evidence. In opposition to “practice,” “theory” often refers to stated principles rather than to what is actually done. There is generally an evaluative implication here, and it can go in either direction. Theory may be held up as an ideal that shames practitioners and/or as something that, if followed, can transform practice. Alternatively, theory may be dismissed as unrealistic or even as mere rationalization. More balanced interpretations are also possible: Here, theory consists of normative principles that provide a general guide for practice, without supplying detailed instructions.

The second contrast, with fact, can also have an evaluative slant in different directions. Theory may be dismissed as speculative and as something to be avoided. This is an attitude found among some EMPIRICISTS. Alternatively, “fact” may be taken to refer to historically constituted appearances that present themselves

as universal and that are therefore systematically misleading. Given this, the role of theorizing is to penetrate factual appearances in order to identify underlying, generative structures, and thereby to show that fundamental social change is possible. This meaning of theory is largely derived from Marxism and CRITICAL THEORY.

The third meaning of theory involves a contrast with evidence or DATA. Here, theories are factual, in the sense of being neither valuational nor speculative. Nevertheless, there is considerable variation. At one end of the spectrum are theoretical frameworks or approaches; examples include BEHAVIORISM, functionalism, rational choice theory, and SYMBOLIC INTERACTIONISM. At the other extreme are specific sets of explanatory principles relating to particular types of phenomena and the conditions under which they occur. An example is differentiation-polarization theory in the sociology of education. This claims that the differentiation of students—for example, through streaming, tracking, banding, or setting—generates a polarization in their attitudes toward school, with those ranked highly becoming more positive and those ranked at the bottom more negative. Of course, other theories lie somewhere between these two extremes. One example would be labeling theory in the sociology of deviance. In specific terms, this claims that, contrary to common belief, labeling and punishing offenders can increase, rather than decrease, the chances of their offending again in the future. However, labeling theory also serves as a theoretical framework, one that emphasizes the importance of studying the labelers as well as the labeled, and requires a suspension of conventional views about what is right and wrong.

Qualifiers are sometimes attached to theory. These may label a particular theoretical approach, such as “critical” or “rational choice” theory. Others mark out a contrast in the level of abstraction involved, as in the case of “grand” and “middle range” theory (Merton, 1968, pt. 1). Other qualifiers are methodological, referring to how theory is produced (e.g., GROUNDED THEORY).

THICK DESCRIPTION

The anthropologist Clifford Geertz popularized the term *thick description* among social scientists, having borrowed it from the philosopher Gilbert Ryle (Geertz, 1973; Ryle, 1971). Both writers reject “thin” descriptions, or those that seek to reduce human actions to observable behavior. The need for thick description stems from the fact that actions are defined by cultural meanings, not by their physical characteristics. For instance, a nervous tick can be contrasted with a wink: The overt behavior may be the same, but the second is an action whereas the first is not. And a wink is different from a parody of a wink, and from somebody practicing winking. As these examples make clear, actions are meaningful, and meaning depends on context—on who is involved in doing what, when, how, why, in response to what other actions or events, with what consequences, and so on. Therefore, Geertz argues, sound description must include the web of meanings that is implicated in the actions being described.

He contrasts thick descriptions not just with BEHAVIORISTIC records of human actions but also with STRUCTURALIST accounts that abstract meanings from their local contexts. He writes that in anthropological work, “theoretical formulations hover so low over the interpretations they govern that they don’t make much sense or hold much interest apart from them” (Geertz, 1973, p. 25). The task in thick description is both to capture the complexity of particular events and to indicate their more general cultural significance. Probably the best known example of a thick description is Geertz’s article “Deep Play: Notes on a Balinese Cockfight” (in Geertz, 1973), in which he uses detailed analysis of a single witnessed event to illuminate distinctive features of Balinese culture.

Geertz proposes that producing thick descriptions should be the primary aim of anthropological research. He insists that such interpretive anthropology is no less a science than physics or chemistry, but that it is a different kind of science. At the same time, he compares the task of the anthropologist with that of the literary critic. In these terms, he suggests, ETHNOGRAPHY is analogous to trying to construct a reading of a manuscript, one that is “foreign, faded, and full of ellipses, incoherencies, suspicious emendations and tendentious commentaries” (Geertz, 1973, p. 10).

The term *thick description* has been adopted by many QUALITATIVE RESEARCHERS as a way of signaling

the characteristic orientation of their work. And the concept has also been used to address the question of how the findings of qualitative studies can be generalized. Thus, Guba and Lincoln argue that thick description is required for readers of qualitative research to be able to assess the transferability of findings to other contexts (Guba & Lincoln, 1985; see also Gomm, Hammersley, & Foster, 2000).

THIRD-ORDER. See ORDER

THRESHOLD EFFECT

The threshold effect takes place in instances where the relationship between two variables appears to seriously change on arriving at a certain value of one or both variables. MODELING the threshold effect is of paramount importance for the analyst in order to describe correctly the relationship between the two variables.

An illustration of the threshold effect is the relationship between the economic system of a country and its level of democratic performance. Assume that one can MEASURE the extent to which a country is capitalist. The measure can be at the ordinal level, as in the “economic freedom” indexes that are put forth by organizations such as the Fraser Institute. It can also be an INTERVAL measure, such as government spending as a percentage of gross national product. With capitalism as the INDEPENDENT VARIABLE, further assume that democracy as the DEPENDENT VARIABLE can be measured on a 0–100 scale, with low scores indicating

Figure 1 Parabolic Relationship of Capitalism to Democracy

the country is less democratic (i.e., less respecting of civil rights and liberties), and high scores revealing a more democratic country (i.e., more likely to hold free and fair elections). Those who believe that there is a threshold effect to the relationship between capitalism and democracy believe, in theory, that capitalism is useful only to a point, whereupon the more capitalist the country, the less democratic it will be. The theory here is that highly capitalist countries, with lower levels of government intervention in the economy, will not be able to provide the social services, the social safety net of welfare spending, or law enforcement that allows for a full expression of democracy in the country.

Empirical studies using OLS regression modeling techniques reveal that, indeed, there is a STATISTICALLY SIGNIFICANT threshold effect of capitalism on democracy, beyond which capitalism has a negative impact on democratic performance in the country. Graphically, the threshold effect is one of an upside down U-shaped curve, with the economic freedom that comes from increasing levels of capitalism in the lower range also increasing democratic performance, up to a point. Beyond the point, the relationship reverses, from positive on the graph to negative on the graph, with higher levels of capitalism actually decreasing democratic performance and forming the right-hand side of the upside down U-shaped curve.

The correct way to model this threshold effect is to take the square of the independent variable—in this case, capitalism—and enter it as a second independent

variable in the model. If there is a threshold effect, then both the linear term and the squared term will achieve conventional levels of statistical significance ($p < .05$, two-tailed test). The mathematical way to calculate the independent variable value at which the threshold effect takes place, with the SLOPE changing from positive to negative on the graph (called the “tipping point”) is to use the formula $-b_1/2b_2$, where b_1 is the OLS REGRESSION COEFFICIENT for the linear term of the independent variable, and b_2 is the OLS regression coefficient for the squared term of the independent variable.

Another illustration of a threshold effect is described by Breen (1996, p. 50). Currency exchange rates are directly observed only when they fall within an upper and lower range of values; in other words, an upper and lower threshold. If the analyst seeks to explain currency exchange rates, then this example is also one of a censored regression model. The analyst can estimate censored regression models using a Tobit estimator.

No matter the example, the analyst will go astray in interpreting the results of parameter estimation without the proper modeling of threshold effects.

THURSTONE SCALING

Thurstone scaling is a covering term representing a series of three techniques developed by psychometrician Louis L. Thurstone during the 1920s. These scaling methods are commonly known as

1. The Method of Equal Appearing Intervals
2. The Method of Successive Intervals
3. The Method of Paired Comparisons

Beneath all of these scaling techniques was a common perspective on the measurement of attitudes—the Law of Comparative Judgment (Thurstone, 1927).

Imagine that you wish to compare the weights of multiple objects and have no modern scale or set of standard weights. Rather than despair about an inability to judge weights precisely, one can estimate the weights of objects relatively—ordering them from lightest to heaviest. This could be done by comparing each object against the others one at a time, judging them in pairwise comparison. Place one object on either side of a balanced beam and identify the heavier object. A full set of comparisons should yield a set of objects ordered by weight. Thurstone was the first to realize and implement a system to do the same thing with psychological rather than physical objects.

A scaling methodology designed to assign numbers to the value or intensity of psychology objects must reflect the discriminations made by individuals judging multiple stimuli. The bottom line underlying the scaling of comparative judgments is that objects that are easily discriminated should be placed further apart than objects that are difficult to distinguish.

The Method of Paired Comparisons involves explicit judgment by all subjects of each combination of objects. This task becomes formidable as the number of objects increases, because the number of paired comparisons rises geometrically. That is, assuming a pairing of A and B is the same as a comparison of B and A, the number of comparisons required equals $N(N - 1)/2$. Four objects will be paired in 6 ways, 5 in 10 ways, 10 in 45 ways. If order matters, the number increases even more rapidly: $N(N - 1)$. Four objects will generate 12 comparisons, 5 call for 20, and 10 require 90. The ordering of a large number of objects becomes unwieldy.

The Method of Equal Appearing Intervals is a technique developed to capture individual assessments of attitude objects without the necessity of capturing all paired comparisons. Judges are employed to calibrate a set of items, which is then administered to the study population.

Begin with a large set of statements reflecting diverse opinions toward an object. Present these statements to a panel of judges, each of whom determines the degree of support for (or opposition to) the object under study by placing the statement in one of 11 ordered piles ranging from “most favorable” to “neutral” to “least favorable.” These initial judgments

provide the basis for the selection of items for the final scale.

Items are ranked in terms of their average support score (MEDIAN) and the variation in support scores (INTERQUARTILE RANGE). Those items that are inconsistently rated by the judges are dropped, and a final scale of 5 to 20 items is created by selecting items covering the range of support and approximately evenly spaced (as presented by the median assessment of the judges).

Equal-appearing intervals scales tend to truncate variation at their extreme points. The Method of Successive Intervals is developed as a check on the assumption made in the procedure for equal interval scaling that all intervals are, in fact, equal. Successive Interval methods allow for unequal intervals to capture extreme positions.

Thurstone scaling methods are limited in several respects:

- *Assumption of unidimensionality.* These scales do not account for the multidimensional nature of attitudes, instead constraining responses to conform to unidimensional structure.
- *Labor intensive.* In exploring attitudes about a stimulus object, the researcher must first create an extensive bank of items representing a range of opinions about the object. The creation of these scales involves considerable work for judges in shifting through items to build final scales.
- *Assumed similarity between judges and subjects.* Judges drawn from populations distinct from those of the focus of study may produce scales that do not apply to the study population.

As a consequence of the weaknesses underlying Thurstonian methods, these scaling techniques are of historical interest more than practical use today.

TIME DIARY. See TIME MEASUREMENT

TIME MEASUREMENT

Time is a social product. All of the human life we know relates itself to rhythms derived from more-or-less regular “time givers” (which might be either natural or artificial: constellations, the sun and moon, church clocks, factory whistles, television programs, family rituals). The different time givers are embodied in different structures of authority, domination, or reciprocity, producing the diverse mixture of time structures through which each individual must navigate during the day. And each person experiences the passage of time differentially according to context and circumstances. Nevertheless, there is a consensual physicists’ time, counted as, for example, oscillations of a pendulum or of a cesium crystal. We are accustomed to measuring the durations of various activities against the passage of this clock time using DIARY methods. “Time budget surveys” involve SAMPLES of diaries allowing researchers to estimate patterns of time use over a given population and calendar period. More than 80 countries have collected nationally representative time diary studies. Szalai (1972) provides a cross-national diary study covering 12 countries; the Multinational Time Use Study now provides microlevel data for 25 countries and various recent historical periods for secondary analysis (Gershuny, 2000).

The diary method mirrors the structure of daily activities. Diary accounts are complete and continuous, so any respondent intending to suppress some activity must make a conscious effort to substitute some other activity. Diaries allow investigation of the activity sequences, or the times of the day at which activities occur. Simultaneous activities can be recorded, and researchers can use them to investigate patterns of co-presence, interdependence, and cooperation. Nevertheless, the time diary method is not unproblematical. In particular, it produces some “under-reporting of socially undesirable, embarrassing, and sensitive” behaviors, including personal hygiene, sexual acts, and bathing (Robinson & Godbey, 1997, p. 115).

There is wide variation in the design of time diary instruments (Harvey, 1999, provides general-purpose design recommendations). There are, as in all obtrusive survey methods, conflicts between the respondent burden (leading to better data but lower response rates) entailed by more extensive and detailed diaries, and the higher response rates permitted by so-called light diary instruments. (Summary results, however, seem quite stable with respect to the different methods; Harvey, 1999.) Particular problems result from daily variation in individuals’ activities. A short (e.g., single-day) diary gives a spurious impression of interpersonal variability that is, in fact, intrapersonal. A longer (e.g., 7-day) diary is more revealing but also much more demanding for respondents.

There are two alternative modes of diary administration, referred to as, respectively, “yesterday” studies, involving an interviewer-led process, and “tomorrow” studies, involving a self-completion instrument. The yesterday diary normally covers the previous day, but despite recall decay, it is possible to collect useable information after a gap of 2 or even 3 days; this may be required to overcome difficulties in interviewing over weekends or short holidays. The tomorrow self-completion diary is left behind with the respondent by the interviewer with the instruction to make records as frequently as possible through the diary period so as to maximize the recall quality. These normally cover either 1 or 2 days, but The Netherlands and the United Kingdom have reasonably successful experience with 7-day diaries. Studies sometimes use a combination of yesterday and tomorrow methods with the self-completion instrument being posted back by the respondent. In this case, the tomorrow approach shows lower and somewhat biased responses. For

tomorrow diaries, response is substantially improved if the interviewer returns to collect the diary.

A further design issue concerns the temporal framework of activity recording. Yesterday diaries often adopt an event basis of recording ("When did you wake up?" "What did you do first?" "What did you do next?"). For self-recording, it is more appropriate to use a schedule with regular time slots of 5 to 15 minutes (although slots of up to 30 minutes have been used, and the length of the slots may vary through the day and night); respondents indicate the duration of each activity on the schedule using lines, arrows, or ditto marks.

Activities may be reported according to a comprehensive "closed" list of precoded activities, or an "open" ("own words") approach. The closed approach may overconstrain respondents, and the choice of categories may, to a degree, influence the level of reporting. But the open approach produces a symmetrical problem: Respondents report at varying levels of detail that are difficult to disentangle from genuine interpersonal differences.

For much of the day, respondents are engaged in multiple simultaneous activities. The normal practice is to ask respondents to record activities in a hierarchical manner: ("What are/were you doing?" "Were you doing anything else at the same time?"). Some studies ask respondents to record all activities in a nonhierarchical manner, but respondents tend to prefer opportunity to use a narrative mode ("First I did this, and then I did that . . ."), which naturally involves the hierarchical approach. The hierarchy also simplifies the process of analysis. Although primary activities are the most frequent focus of analytical attention, it is also possible to represent combinations of activities nonhierarchically while still conserving the 1440 minutes of the day.

Other ancillary information included within the rows or columns of diary forms include co-presence ("Who else is engaged with you in this activity?") and current location (or modes of transport). Specialized diary studies also include interpretive or affective information (e.g., "Is this work?" or "How much did you enjoy this?") attached to each event or activity.

Beyond the design of the diary instrument, there are also various specialized sampling issues. Seasonal effects may be of importance; representative samples of time use require an even coverage across the year. Conventional tomorrow studies have included children down to the age of 10.

An alternative approach to the measurement of time use involves "stylized estimates" ("How much time do you spend in . . .?") as part of questionnaire inquiries. This approach is the simplest and cheapest way to collect information about how people use their time, and it is widely used (e.g., in national labor force surveys). But it has significant drawbacks. Research on the paid work time estimates deriving from this methodology suggests systematic biases, particularly overestimates of paid work time (Robinson & Godbey, 1997, pp. 58–59).

ETHNOGRAPHIC research has often involved direct observation of people and the recording of their activities by the researchers. New technology now extends the role of direct observation, including such unobtrusive devices as individual location monitoring systems and closed-circuit or Internet camera systems. Observational methods have advantages, but they are costly and labor intensive, and they may compromise personal privacy. Moreover, people can be expected to censor or distort their normal patterns when aware of continuous monitoring.

TIME-SERIES CROSS-SECTION (TSCS) MODELS

TSCS models aim to detect the causal processes underlying TSCS data (often called PANEL data). One can represent such data as a three-dimensional "data cube" in which cases, variables, and time points are the dimensions (see Figure 1). TSCS data sets contain more information than either (a) CROSS-SECTIONAL DATA sets comprising data on variables for cases at a single time (e.g., the front slice of the cube in Figure 1), or (b) TIME-SERIES data sets comprising data

on variables at times for a single case (e.g., the top slice of the cube in Figure 1).

Researchers sometimes compile TSCS data sets because a target population has a small number of cases. For example, any cross-sectional study of European nation states will be limited by the fact that it will have fewer than 30 cases, severely restricting one's ability to carry out multivariate statistical analyses. By collecting data for those cases at several time points rather than just one, a researcher may be able to obtain enough additional observations to facilitate better analyses.

TSCS data sets are also attractive because of their analytic potential. For example, using TSCS data, one may be able to assess whether an independent variable's effect on a dependent variable changes over time (not possible with cross-sectional data), or whether an independent variable's effect differs across cases (not possible with simple time series data). Finally, researchers frequently use TSCS data in order to control for case-stable unmeasured variables, an important type of unmeasured HETEROGENEITY, in multivariate analyses.

The analytic flexibility that TSCS data affords is not unlimited, however. To gain an advantage from pooling time series and cross-sectional data, there must be reason to assume some kind of invariance in the effects, including nonlinear and nonadditive effects, of the independent variables. These effects need to be constant across cases, across time, or both (in practice, most researchers assume both kinds of invariance). In addition, in TSCS analyses, both HETEROSKEDASTICITY, primarily seen as a potential problem for cross-sectional STATISTICAL INFERENCE, and AUTOCORRELATION, primarily seen as a potential problem for time series statistical inference, are possible threats to statistical inference.

LARGE-*N*, SMALL-*T* TSCS MODELS

Given the many analytic opportunities afforded by TSCS data, there are many possible TSCS models. Two general classes of models exist, however,

Figure 1 A Data Cube Representation of a Time Series Cross-Section Data Set

corresponding to whether the number of cases (n) substantially exceeds the number of time points (t), or vice versa. Large n panel studies, such as the National Longitudinal Study of Youth and the Panel Study of Income Dynamics in the United States, have thousands of cases and relatively few (i.e., < 15) time points. Studies using such data typically view unmeasured heterogeneity among the cases as the most important potential source of estimator bias and inconsistency, and address this problem using either fixed effects (FE) or random effects (RE) estimation procedures. Both sets of estimation procedures stem from the analytic model:

$$Y_{it} = \beta_0 + \beta_1 X_{1it} + \beta_2 X_{2it} + \cdots + \beta_k X_{kit} + \alpha_i + \varepsilon_{it},$$

where i indexes cases, t indexes times, and numerical subscripts index the measured independent variables (X), with β_0 standing for the equation's intercept term. As usual, ε_{it} represents a DISTURBANCE TERM with a mean of zero, constant VARIANCE, and no ASSOCIATION with the independent variables in the equation. The α_i represent the effects of unmeasured variables that are stable across time for each case, but vary across cases. In studies where individuals are cases, for example, this term would represent stable but unmeasured variables, such as innate ability or physical attractiveness, that affect cases' values on the dependent variable.

The FE estimator for this model includes the α_i among the independent variables in the equation, either directly—as a set of $n - 1$ dummy variables representing the n cases—or indirectly—as a case-specific “time demeaning” of the measured variables in the analysis (Wooldridge, 2000, pp. 441–446). Because the α_i represent variables that are stable over time for each case, using the fixed effects estimator makes it impossible to estimate partial effects for stable, *measured* independent variables, such as gender and race/ethnicity. Most researchers consider this a small price to pay for the ability to control for the effects of myriad unmeasured stable variables, however. (The first-difference estimator—see Wooldridge, 2000, pp. 419–425—although closely related to the fixed effects estimator, is used less often, even though in some situations it may have superior statistical properties; Wooldridge, 2000, pp. 447–448.)

The RE estimator for large- n , small- t TSCS data sets assumes that α is a random variable and leaves it in the equation’s error term, thereby creating a composite error term $u_{it} = \alpha_i + \varepsilon_{it}$. This approach has three important implications. First, the RE estimator is biased and inconsistent unless the variables that α represents are unrelated to the measured independent variables in the analysis. Many researchers find it difficult to assume that α will fulfill this condition and therefore prefer FE. For example, physical attractiveness (usually unmeasured) is probably positively correlated to personal income (usually measured). Second, when case-stable variables are left in the composite error term, one must use feasible GENERALIZED LEAST SQUARES estimation techniques (FGLS) to take into account the fact that the disturbance terms for each case will be correlated across time. Fortunately, many statistical packages (e.g., SAS, Stata) include a program to carry out this FGLS procedure. Third, the inclusion of α in the composite error term makes it possible to estimate partial effects for measured independent variables that vary across cases but not across time, which is impossible when one uses FE.

If α is unrelated to the measured independent variables in one’s analysis, RE will be more efficient than FE because it estimates only one additional quantity (the variance of α) beyond the standard OLS estimates. In contrast, FE estimates an additional $n - 1$ quantities when it estimates each of the α_i . Researchers frequently use a Hausman test to determine whether α is unrelated to the measured independent variables in an analysis (Wooldridge, 2002, pp. 288–291), and

thus whether using the potentially more efficient RE estimator is justifiable.

The model above can be extended to include a term for unmeasured time effects as well as unmeasured case effects. In this case, the model becomes

$$Y_{it} = \beta_0 + \beta_1 X_{1it} + \beta_2 X_{2it} + \cdots + \beta_k X_{kit} + \alpha_i + \nu_t + \varepsilon_{it},$$

where ν_t represents the effects of unmeasured variables that are constant across cases at a given time. Subject to the same advantages and disadvantages outlined above for the model containing only α_i , one can use FE, RE, or a combination of FE and RE to estimate this model.

SMALL- N , LARGE- T TSCS MODELS

Researchers analyzing TSCS data sets with small numbers of cases and many time points typically focus on heteroskedastic and autocorrelated disturbances as the chief threats to valid inference, and take advantage of the many observations per case to estimate FGLS models that adjust for these threats. At a minimum, such models incorporate casewise heteroskedasticity and a common autocorrelation pattern across cases, but many other possibilities exist. For example, one popular alternative, the Parks-Kmenta model, incorporates casewise heteroskedasticity, case-specific levels of AR1 autocorrelation, and time-specific correlations among the disturbances for different cases. Estimation of complicated disturbance structures require data on many time points, however, and Monte Carlo experiments suggest that estimation of the Parks-Kmenta model can produce seriously misleading statistical tests when the number of time points is fewer than 40 (Beck & Katz, 1995). Most econometric statistical packages include a range of alternative models for analyzing small- n , large- t TSCS data.

TIME-SERIES DATA (ANALYSIS/DESIGN)

Time-series data arise frequently in the study of political economy, macroeconomics, macropolitical sociology, and related areas. Time-series data are repeated observations, at regular intervals, on a single entity, such as a country. They are distinguished from CROSS-SECTIONAL DATA, which consist of observations on a sample of entities (perhaps individuals or countries) at one point in time. Although some analysts analyze a single time series (see BOX-JENKINS MODELING), most use time-series data to study the relationship between a dependent variable and one or more independent variables, as in the typical REGRESSION. For simplicity, this entry considers only a single independent variable, although everything said generalizes easily to a MULTIPLE REGRESSION. Because time-series models are a type of regression model, all of the issues related to regression models apply, including testing, SPECIFICATION, and so on. This article focuses on issues specific to the analysis of time-series data by discussing, first, some examples of time-series data; then some issues in estimation; and, finally, some issues in specification and interpretation (see also LAG STRUCTURE), with a brief discussion of further directions in the concluding section.

EXAMPLES OF TIME-SERIES DATA

Macroeconomists are the most common users of time-series data. Typically, they have monthly or quarterly observations on a variety of economic phenomena and are interested in relating, say, some policy instrument, such as the money supply, to some economic variable of interest, such as the growth of GDP. Similar analysis is undertaken by political economists and sociologists who are interested in the relationship of political variables, such as the political orientation of the coalition in power, to economic outcomes, or the relationship of economic variables, such as unemployment or inflation, to political outcomes, such as presidential popularity or the outcome of elections. Time-series data arise in many other areas, such as the study of conflict, where studies analyze the causes of defense expenditures over time. In all of these studies, analysts must be aware of the frequency of their data, be it daily, monthly, quarterly, or annually; different

models are appropriate for data of higher or lower frequency.

This entry limits itself to discussing stationary time series. Roughly speaking, a time series is stationary if its various statistical properties do not change over time; in particular, the best long-run forecast of a stationary series is its overall mean. Nonstationary series involve much more difficult mathematics; causes of nonstationarity usually involve some type of time trend. Analysts must be careful that they limit their use of stationary methods to stationary time series.

Although time-series data refer to observations on a single unit, they can be generalized to TIME-SERIES CROSS-SECTIONAL DATA, where analysts study time series obtained on a variety of units, usually having annual observations on a set of countries. Time-series cross-section data have some time-series properties, and so many issues relevant in the estimation of time-series models are also relevant. PANEL data are also related to time-series data; there, the analyst usually has only a few repeated observations on a large number of individuals. Although panel data present estimation problems related to time-series issues, the data are sufficiently different that different models and approaches must be used.

ESTIMATION

Stationary time-series data are estimated using standard regression methods. If the data meet all of the assumptions for such methods, then ORDINARY LEAST SQUARES has its usual optimal properties. But time-series data usually do not meet one critical assumption—that the observations are independent of each other (or, equivalently, that the error terms for each observation are independent). Time-series data observed at closely spaced intervals (perhaps a month) in general will be highly interdependent; data observed at intervals far apart (say, a decade) might well be independent.

Dependence has serious consequences for estimation. Fortunately, it is easy to both test for this dependence and correct for it. Failure to do so can lead to highly inefficient estimates and highly inaccurate standard errors. Although violating some assumptions may not be serious, violations of the independence of error terms assumption can easily lead to mistakes of several hundred percent. Thus, time-series analysts must be very careful to both test and correct for dependencies among observations. The typical assumption

is that observations observed one time period apart are the most related, with that relationship declining as the two observations are observed further and further apart. Letting the error term for an observation at time period t be denoted ε_t , assume a simple regression model:

$$y_t = \alpha + \beta x_t + \varepsilon_t.$$

The simplest assumption about the errors is that they follow a first-order, autoregressive (AR1) pattern, that is,

$$\varepsilon_t = \rho \varepsilon_{t-1} + v_t,$$

where the v_t are assumed to be independent of each other. ρ is then a measure of how highly correlated the errors are.

Analysts can test the hypothesis $H_0: \rho = 0$, that is, that the errors are independent, by estimating the regression model and capturing the RESIDUALS. Independence can then be assessed by the famous DURBIN-WATSON STATISTIC or, more simply, by regressing the OLS residuals on their lags, plus all other independent variables, and then assessing the significance of the coefficient in this auxiliary regression. This is the simplest example of a Lagrange multiplier test; such tests are extremely useful in the analysis of time series.

If the null hypothesis of independence is not rejected, time-series data can be estimated by OLS (assuming the other assumptions are met). But if the null hypothesis of independence is rejected, as it often will be, then OLS is seriously flawed. A good alternative is GENERALIZED LEAST SQUARES. For time-series data with AR1 errors, generalized least squares is essentially the famous Cochrane-Orcutt procedure. This proceeds in five steps:

- Use OLS on the basic regression equation.
- Use the residuals from that regression to estimate ρ (by regressing the residuals on the lagged residuals).
- Use that estimate to “pseudo-difference” the observations (i.e., take the current observation and subtract the estimated ρ times the previous observation).
- Redo OLS, estimating a new value of ρ .
- Iterate Steps 3 and 4, stopping when the estimate of ρ does not change.

This procedure provides good estimates of α and β and correct standard errors.

Often, we add last period’s observation of y , the lagged dependent variable, y_{t-1} , to the specification, giving

$$y_t = \alpha + \beta x_t + \varpi y_{t-1} + \varepsilon_t.$$

Although the Durbin-Watson test no longer works with a lagged dependent VARIABLE, the Lagrange multiplier test discussed continues to be a good test of whether the errors are independent. It is often the case that errors in the lagged dependent variable model are independent, in which case the model is well estimated by OLS. But analysts must use the Lagrange multiplier test to examine the hypothesis of independence: If the errors are dependent, then OLS is not even consistent.

If x and y are not stationary, then all standard methods fail. Roughly speaking, analysts can assess stationarity by regressing x on its first lag and then examining the estimate of the regression coefficient (and similarly for y). If the coefficient is close to one (a UNIT ROOT), then analysts must use much more complicated methods, well beyond the scope of this entry. However, one model that often works well with such data is the ERROR CORRECTION MODEL, which assumes that there is a long-run equilibrium relationship between x and y as well as a short-run relationship, so that the estimated model is

$$\Delta y_t = \alpha + \beta \Delta x_t - \phi(y_{t-1} - \gamma x_{t-1}) + \varepsilon_t.$$

The term in parentheses is the amount that the system was out of equilibrium, and ϕ is the speed of adjustment back to equilibrium. Under many conditions, this model can be estimated by OLS. However, nonstationary series are complicated, and analysts must be very careful to use appropriate methods and models in this highly technical field.

Finally, it should be noted that the above is limited to models where effects either are all felt immediately or work with a one-period lag. It is easy to generalize this to more complicated LAG STRUCTURES. Although it is often the case that one-period lags suffice for annual data, quarterly or monthly data frequently require much more complicated lag structures. Here, still, the principles of testing remain similar. There are many additional tools available, such as the correlogram, to aid the analyst in deciding how many lags to include in the model.

SPECIFICATION AND INTERPRETATION

In a simple regression, the regression slope, β , tells us that if x changes by one unit, y is expected to

change β units. This is true for simple time-series models, but such models can also have more complex specifications. Thus, for example, in the lagged dependent variable model, a one-unit change in x is associated with an initial change of β units in y , but the effect of a change in x persists over time. Suppose that x goes back to its initial value in the next period. In this period, though, the lagged y is now β units higher, so the current y is $\beta\omega$ units higher. In the next period, the lagged y is $\beta\omega$ units higher, so the current y is $\beta\omega^2$ units higher, and so forth. The graph of this function is called an impulse response function.

Alternatively, we could allow for x to change one unit and stay at that new level forever (level change analysis). How, then, does y respond? Initially, y goes up by β units. In the next period, lagged y is β units higher, but x is still one unit higher, so y is $\beta + \omega\beta$ units higher. The following period, x is still one unit higher, and y is now $\beta + \omega\beta$ units higher, so y is now $\beta + \omega(\beta + \omega\beta) = \beta + \omega\beta + \omega^2\beta$ units higher. This geometric progression continues, and so, by simple algebra, a one-unit change in x is eventually associated with a $\beta/(1 - \omega)$ -unit change in y . (This assumes that $\omega < 1$, which is a necessary condition for stationarity.) Thus, if ω is large (say, 0.9), the long-run impact of a unit change in x is 10 times the short-run impact, β . It is critical to keep this interpretation in mind. All time-series models should always be interpreted with both impulse response and level change analyses. (It is important to remember that all of the coefficients used are estimated, and so estimated effects have confidence intervals.)

Such analysis is most useful in thinking about the appropriate specification of a time-series model (as opposed to the technical impediments to estimation discussed in the previous section). Thus, although the generalized least squares solution discussed above correctly deals with estimation problems, an impulse response analysis shows the potential defects of this model. In particular, a unit change in x has an immediate impact on y of β units, with that impact disappearing immediately. But a one-unit change in ε , the error, has an immediate one-unit impact on y , which decays at a rate of $(1 - \rho)$ percent per period. Thus, the error term has very complicated dynamics, but the variable of interest, x , is posited to have only an immediate impact, with no dynamics. Although this could be a correct description of the process, on its face it seems implausible. The lagged dependent variable

model, on the other hand, shows the same dynamics and decay rate for changes in both x and the error term; on its face, this is more plausible.

There are clearly many possible specifications that analysts must consider. These can be compared in terms of both their theoretical properties as well as how well they fit the data. In either enterprise, models with a lagged dependent variable will often be strong competitors. Thus, it is important to remember that models that contain a lagged dependent variable *and* dependent errors cannot even be estimated consistently by OLS (and so any generalized least squares procedures that start with OLS estimates will also be wrong). Fortunately, it is easy to use the Lagrange multiplier tests to examine whether the errors are correlated in models with lagged dependent variables; nicely, such tests work with the OLS residuals. Although such tests often show no remaining correlation of the errors, analysts must be rigorous in using them before continuing work.

NEW DIRECTIONS

The analysis of a single stationary time series is now well understood. It is often the case that OLS works well for such series, and a rigorous Lagrange multiplier testing strategy always indicates when OLS will not work well. When it does, time-series models are easy to estimate, and analysts can focus on finding the appropriate lag structure (sometimes theoretically, usually empirically) and studying the properties of the estimated model by impulse response and level change analyses. Theoretical interest rests on the choice of a particular lag structure to estimate.

Much research in the past decade has focused on nonstationary time series, particularly those with unit roots. Economists have concentrated on using these models to decompose time series into trends and cycles; such decompositions have long been of interest to macroeconomists. Attention has also focused on analyzing multiple time series, such as exchange rates between various countries, to see whether the trends and cycles they show are common or distinct. The estimation of all these models is technically difficult, but now implemented in standard time-series software packages. But for analysts trying to explain a single dependent variable that is nonstationary, the simple error correction model often suffices (and tests can indicate whether it does suffice). The advantage of

the error correction model is that it can be estimated by OLS.

Much attention has been paid recently to analyzing panel and time-series cross-section data. Panel data usually have relatively few repeated observations on the same individual, and so it is usually impossible to use sophisticated time-series models on the data. But attention must be paid to the interdependence of the observations on the same individual over time. Time-series cross-section data, however, typically have enough observations per unit so that it is possible to use at least some time-series methods and models to analyze the data. This is an area of great interest to those interested in comparative methods, whether in economics, sociology, or political science. Recently, there has been a spate of activity in the analysis of time-series cross-section data with a binary or other limited dependent variable; this activity has largely taken place in the study of political conflict. These are all areas of intense research, but much of that research begins with the analysis of a single time series.

TOBIT ANALYSIS

In defining Tobit, James Tobin (1958) quoted a passage about how nothing could not be less than nothing. Tobit permits analyzing dependent variables with zero as their lowest value and that are from CENSORED DATA, and it avoids violating ORDINARY LEAST SQUARES' (OLS) continuity and unboundedness assumptions about DEPENDENT VARIABLES. OLS can produce negative predicted values for such dependent variables and predict something that is less than nothing. Other consequences of using OLS

include biased coefficients and incorrectly obtaining statistically insignificant coefficients. Obtaining negative predicted values is the most common problem that Tobit solves, but it can analyze dependent variables with upper, upper and lower, and intermediate limits.

Tobit combines PROBIT ANALYSIS with OLS. Its coefficients allow identifying two effects on a dependent variable: (a) an effect on the probability of exceeding its limiting value(s), and (b) an effect on changing values beyond the limit (McDonald & Moffitt, 1980). For example, neighborhood crime rates cannot be less than zero, but they can have any positive value. For small areas, many will have crime rates of zero. OLS could predict negative crime rates, which are nonsensical (except for burglaries once a year). Manipulating Tobit coefficients permits identifying the effects of INDEPENDENT VARIABLES on the probability of a crime where the crime rate is zero and on changing the crime rate for places with nonzero rates. Tobit adjusts for the inability to measure a dependent variable's values beyond some limit, such as zero, and produces unbiased estimates of the independent variables' effects.

Tobit is a large-sample technique. The case-to-variable ratio should be 10 or more. It can be sensitive to the measurement of independent variables. These should have similar ranges even if transformations are necessary. Its sensitivity to heteroskedasticity can be tested and adjusted for by programs such as LIMDEP. The dependent variable should be continuous beyond its limit value, although Tobit can, at times, model more accurately the distributions of count variables than POISSON REGRESSION. Tobit requires the same signs for the effects it provides. The expected change in probability of having a crime in a no-crime area must be the same as that for the expected change in crime in areas with crimes. Otherwise, different techniques must be used.

The sum of the intercept and products of Tobit coefficients with their independent variables' values can be negative. Tobit coefficients are effects on an unobserved ("latent") variable. Their decomposition allows interpreting the effects on a dependent variable's observed values. The coefficients' sizes depend on the independent variables' measurement scales. Larger coefficients do not always indicate more important independent variables. Modifying Roncek's (1992) pseudostandardized coefficient by multiplying a Tobit coefficient only by the standard deviation of its independent variables adjusts for its measurement scale.

Dividing each coefficient by the dependent variable's standard deviation or the Tobit model's standard error is irrelevant.

TOLERANCE

Tolerance is a measure that aids in assessing the degree of MULTICOLLINEARITY in a REGRESSION model. It indicates the amount of variation in an INDEPENDENT VARIABLE *not* statistically accounted for by the other independent variables in the model. If Tolerance = 1.0, then the independent variable in question has complete linear independence from the other independent variables in the model. If Tolerance = 0.0, then the independent variable in question has complete LINEAR DEPENDENCE on the independent variables in the model. The higher the Tolerance value, the less multicollinearity there is. Tolerance is routinely calculated in some statistical packages. In general, the analyst can regress each independent variable, j , on all the other independent variables in the model, not j , yielding an R -SQUARED accounting of X_j . Then, from this auxiliary regression, the $R^2_{X_j} = 1 - \text{Tolerance}$. For example, if $R^2_{X_j} = 0.65$, then Tolerance = 0.35.

TOTAL SURVEY DESIGN

Total survey design is all of the elements of a social SURVEY that can affect estimates from that survey: the SAMPLE of people selected to be in the survey, the characteristics of those from whom data were

actually collected, the design of the questions, and the procedures that were used to ask questions and get answers.

The concept of total survey design pertains to social surveys that are designed to produce statistical descriptions of some POPULATION. Such surveys usually have the following characteristics: (a) A sample of the population to be described, not the whole population, is chosen to provide information; (b) only some fraction of those asked to provide information actually do so, the “RESPONDENTS”; (c) the data consist of the answers that chosen respondents provide to questions that are posed; and (d) the question-and-answer process is carried out either by having an interviewer ask questions and record answers or by having respondents themselves read questions, from a paper form or off of a computer, and record their answers on that paper form or directly into the computer. Each of those elements of the social survey has the potential to affect how well the results from the survey describe the population that is being studied. For example:

- a. Who has an actual chance to be selected to be in the sample, and how they are chosen, is critically important to how likely the sample is to mirror the population from which it is drawn.
- b. Those who actually respond to the questions may be systematically different from those who cannot or choose not to in ways that affect the survey results (see NONRESPONSE).
- c. The size of the sample, the number of people who actually respond, will affect the precision of estimates made from the sample results.
- d. Which questions are asked, and how well they are designed, will have a major effect on how well the answers to those questions provide valid information about what the survey is trying to measure.
- e. If interviewers are involved in data collection, the quality of INTERVIEWING—how well they carry out their roles—can affect the accuracy of the resulting data.
- f. If the questions are self-administered, with respondents reading them and providing answers themselves, how well the forms or programs are designed can affect the quality of data that result from the survey.

The fundamental premise of total survey design is that the data from a survey are no better than the worst elements of the methods used. When designing a survey, when carrying out a survey, or when evaluating the data from a survey, it is important to look at all of the elements of the survey that could affect data quality, the total survey design, when making choices about how to conduct that survey or estimating how accurate the resulting data are likely to be.

TRANSCRIPTION, TRANSCRIPT

Although it is now possible to store, code, and retrieve audio and audiovisual data in digital form, most interview-based QUALITATIVE RESEARCH continues to rely on the *transcription* of audiotaped material into textual form. Therefore, the production of accurate and high-quality *verbatim transcripts* is integral to establishing the credibility and trustworthiness (rigor) of qualitative research. Errors that reverse or significantly alter the meaning of what was said are the most problematic because they may lead the researcher to misinterpret and misquote respondents.

A review of sources of transcription errors (Poland, 1995) suggests that these arise most commonly (and are most difficult to detect) when alternative wordings, at least superficially, still make sense. This can occur, for example, when some words are mistaken for others with similar sound but very different meaning (e.g., “consultation” and “confrontation”); when inserting punctuation in ambiguous situations (e.g., “I hate it, you know. I do.” vs. “I hate it. You know I do.”); or when people mimic the speech of others (or conversations they have in their heads), and therefore, views that are not really their own appear as if they are. Transcriber fatigue; poor-quality recordings (due to background noise, use of low-quality tapes and microphones, poor microphone placement); and difficulty understanding accents and culturally specific turns of

phrase can also contribute to transcription errors. When material is produced by professional transcribers rather than by the researcher who conducted the interview, lack of familiarity with the subject matter or with the interview respondent and the interview itself often pose additional challenges.

Measures to enhance the quality of transcription include ensuring high-quality audio capture; attention to the selection and training of transcribers; the use of notation systems to capture pauses, emphasis, and other aspects of verbal interaction; MEMBER VALIDATION; and procedures for the post hoc review of transcription quality. The amount of time and energy put into producing verbatim transcripts (indeed, decisions about how verbatim is sufficient) depends on the requirements of the researcher. The needs of those engaged in CONVERSATION ANALYSIS, for example, typically exceed those of other qualitative researchers whose interest may be in the gist of what was said rather than in the analysis of the structure and form of naturally occurring talk.

Attention to issues of transcription quality need to be tempered with an understanding of what is inherently lost in the process of translating across media. Text on a page cannot recreate the full tenor and feel of an interview, and those who measure accuracy of transcription against the audiotapes from which they are derived would do well to remember that most nonverbal (and some verbal) communication is already missing from interview tapes. Indeed, a number of voices within the small but growing literature on transcription have sought to problematize the commonplace emphasis on the production of “verbatim” transcripts. Arguing for a more reflexive stance, they underscore the importance of seeing transcription as an interpretive act involving the selective emphasis and coding of data, and not simply as a technical issue of maximizing accuracy.

Finally, because of the inherent differences in standards of communicative competence between spoken and written language, an insistence on verbatim transcription that is carried over into the use of quotations in published research can inadvertently portray respondents as less articulate than they would be if they had written on the subject themselves. In cross-cultural and interclass research in particular, this can have important political and ethical ramifications.

TRANSFER FUNCTION. See BOX-JENKINS MODELING

TRANSFORMATIONS

Transformations are used to change the characteristics of VARIABLES by reducing the number of categories, combining variables, or changing the metric of the variable. Prior to conducting the actual analysis of DATA, substantial amounts of time are spent in data processing. A major component of data processing involves variable transformation.

Transformations are used to collapse categories of nominal or ordinal data to obtain a smaller, more usable number of categories. If univariate statistics indicate that few observations fall in some categories of a variable, it may be sensible to combine them with similar categories. For nominal data, any categories can be combined, but for ordinal data, only adjacent categories should be combined. The decision to collapse categories is a compromise between having too many categories, with some containing few observations, and collapsing data into so few categories that valuable information is lost.

Transformations are also used to change the CODES on variables without collapsing categories. For example, log linear analyses are more easily interpreted if dichotomous categories are transformed into codes with 0 and 1. Categorical variables with three or more categories are often transformed to a series of DUMMY VARIABLES with only two outcomes (0 or 1) for use in MULTIVARIATE ANALYSES (Afifi & Clark, 1999). Transformations are also used to change the units of interval or ratio data, to sum or otherwise combine

variables to create a scale or other summary score, to create combinations of variables, and to summarize skip patterns.

One of the simplest operations is arithmetic transformation. All package programs used for data processing and analysis can perform addition (+), subtraction (−), multiplication (*), division (/), and exponentiation (**) (raising a variable to a power—for example, squaring it). In addition to the arithmetic operations, most software packages have numerous *functions* that can be used in data screening, transformations, and statistical analyses. Commonly used functions include taking the log of a variable; computing the mean of a variable; determining the maximum and minimum of a variable; assigning random numbers; recoding dates; and generating cumulative distribution functions of common DISTRIBUTIONS, such as the normal. These functions can be used in combination with the arithmetic operations. For example, “ $z = \log(y + 100)$ ” would result in a new variable called z being computed from the log of the sum of variable y plus 100.

Comparison operators are also heavily used in transforming variables or for case selection. These operators compare two or more variables, constants, or functions. They are used in *if-then* or *if-then-else* statements. Commonly used comparison operators include the following: gt , $>$ (greater than); ge , $\geq$ (greater than or equal to); lt , $<$ (less than); le , $\leq$ (less than or equal to); eq , $=$ (equal); ne , $\neq$ (not equal to); and, $\&$ (both or all true); or, $|$ (either true).

Finally, transformations are commonly used to achieve approximate univariate normality out of a SKEWED or nonnormal distribution. There are several strategies to determine the appropriate transformation. For example, the square root transformation is commonly used for data that follow a POISSON DISTRIBUTION. When the researcher does not know the theoretical distribution that the data follow, power transformations should be considered (Hoaglin, Mosteller, & Tukey, 1983; Tukey, 1977).

TRANSITION RATE

A transition rate, also known as a “transition intensity” and as an “instantaneous rate of transition,” is a concept that primarily arises when researchers want to distinguish COMPETING RISKS while conducting SURVIVAL ANALYSIS or EVENT HISTORY ANALYSIS. Interest in differentiating among competing risks originally came about in studies of the causes of death and failure. Not surprisingly, equivalent older names for a transition rate are the “cause-specific force of mortality (failure)” and the “cause-specific mortality (failure) rate.” Because the mathematical definition of a transition rate is closely related to the definition of a HAZARD RATE, some authors do not distinguish between the two terms.

Formally, a transition rate to a certain destination state k from a given origin state j at a particular time t is defined as

$$r_{jk}(t) = h_j(t)m_{jk}(t),$$

where $h_j(t)$ is the hazard rate of *any* transition from state j at time t and $m_{jk}(t)$ is the conditional probability that the transition (i.e., the event) consists of a change or move from state j to state k at time t . Like a hazard rate, a transition rate is measured as the inverse of time (e.g., per month or per year). Also like a hazard rate, a transition rate cannot be negative, but it may exceed one.

To give a few examples, if j denotes being married, k signifies being divorced, and time t refers to a person’s age in years, then $r_{jk}(t)$ would indicate the instantaneous rate per year at which a currently married person who is age t becomes divorced. As another example, if j denotes being unemployed, k represents having a job as a skilled worker, and t indicates the duration of a person’s unemployment in months, then $r_{jk}(t)$ would stand for the instantaneous rate per month at which a person who has been unemployed for a length of time t enters a job as a skilled worker.

ESTIMATION of a transition rate involves relatively minor modifications of the formulas for estimating the hazard rate of the occurrence of any event. A traditional demographic estimator of the transition rate associated with a specified discrete time interval $[u, v]$ is called the life table or actuarial ESTIMATOR; it is defined as

$$\widehat{r_{jk}(t)} = \frac{d_{jk}(u, v)}{(v - u)\{n_j(u) - \frac{1}{2}[d_{jk}(u, v) + c_j(u, v)]\}},$$

$$u \leq t < v,$$

where $d_{jk}(u, v)$ is the number of transitions from j to k in the interval $[u, v]$; $n_j(u)$ is the number that have survived in state j until time u ; and $c_j(u, v)$ is the number in state j at time u who are censored on the right before time v . The multiplier of one-half in the denominator on the right-hand side of this equation comes from assuming that the transitions and censored observations are spread uniformly over the interval $[u, v]$. A common, modern estimator is based on the Nelson-Aalen estimator of the integrated hazard rate:

$$\widehat{r_{jk}(t)} = \frac{d_{jk}(u, v)}{(v - u)n_j(u)}, \quad u \leq t < v.$$

For a mathematical introduction to these and other estimators of a transition rate, see Cox and Oakes (1984, Chap. 9). For a longer and less technical discussion addressed to social scientists, see Tuma and Hannan (1984, Chap. 3).

Typically, transition rates are modeled using a variant of a proportional hazard rate model (see Tuma & Hannan, 1984, Chaps. 5–8),

$$r_{jk}(t) = q_{jk}(t) \exp[\beta'_{jk}x_{jk}(t)],$$

where $q_{jk}(t)$ may be either a specific function of time (in a fully parametric model) or an unspecified nuisance function (in a partially parametric Cox model); $x_{jk}(t)$ is a possibly time-varying set of explanatory variables thought to affect the transition rate, and β_{jk} is a set of parameters giving the corresponding effects of the explanatory variables. Such models are usually estimated by MAXIMUM LIKELIHOOD or (in the case of the Cox model) by partial likelihood. Non-proportional models are often appropriate but are used less frequently in empirical applications; see Wu and Martinson (1993) for an example.

TREATMENT

This topic comes from the area of design and analysis of EXPERIMENTS. The term is used in two ways—either as an INDEPENDENT VARIABLE in the study of the effect of a variable on a DEPENDENT VARIABLE, or as a particular value of an independent variable. In spite of its double meaning, the term is so embedded in the literature on experiments that it will continue to be used. It is usually clear from the context whether the term is used as a variable or a value of a variable.

As a variable, the treatment is often a nominal-level variable. With just one experimental group and a control group, the units in the experimental group all get the treatment, whereas the units in the control group do not get the treatment. It is also possible to have more than two values of the independent variable. With two different teaching methods, the children in the first group get Treatment A, the children in the second group get Treatment B, and the children in the control group get no treatment. Here, treatment is used as a value of the NOMINAL VARIABLE. The outcome variable can be a reading score measured as a quantitative variable.

Data from an experiment of this type are commonly analyzed using ANALYSIS OF VARIANCE. These were the types of data with which Sir Ronald A. Fisher worked when he did his pioneering work on the design and analysis of agricultural experiments.

The treatment in an experiment can also be a QUANTITATIVE VARIABLE. For example, in a medical experiment, the treatment can be the injection of a medication. The first group can be patients given an injection of 5 mg, patients in the second group a dose of 10 mg, and so on. Again, the control group does not get any medication, except perhaps for an injection of sugar water as a placebo. The outcome variable can be a quantitative blood test of some type. Here, the term *treatment* has already been used in its second

meaning—as the particular value of an independent variable. A particular teaching method is a treatment, and a particular dosage of a medication is a treatment.

Data from an experiment of this latter type are commonly analyzed using REGRESSION analysis. A SCATTERPLOT will reveal whether the data fit a linear model or whether some other model is more appropriate.

The implication of the term *treatment* is that there is something in the research that can be manipulated by the researcher. Such manipulations are not used for observational data, and we do not see the term used for independent variables or values of these variables in sample surveys and other uses of observational data.

Apart from certain areas of psychology, experimentation is not anything commonly used in the social sciences, and the term *treatment* is therefore not used much in these sciences.

TREE DIAGRAM

In graph theory, a *tree* is defined as a completely connected graph without cycles. Like any other graph, a tree diagram consists of a set of nodes connected by a set of arcs. Some nodes in a tree are internal nodes that have two or more arcs emanating from them. Other nodes are external nodes, or “leaves” of the tree, with only a single arc emanating from them. For example, in Figure 1(a), nodes *A*, *B*, *C*, and *D* are the leaves, and nodes *e*, *f*, and *g* are internal nodes. Sometimes, for graphical convenience, tree diagrams are presented in parallel form, as in Figure 1(b). Here, the arcs of the tree are represented only by the horizontal lines of the diagram, and the vertical lines are merely to connect the arcs.

In the social sciences, tree diagrams are used to represent relationships among concepts or entities. For example, tree diagrams may be used to represent the structure of certain social NETWORKS (Wasserman, 1994). Perhaps more commonly, trees are used to

Figure 1 Two Displays of an Ultrametric Tree

represent the results of hierarchical CLUSTER ANALYSES. In these representations, usually the leaves of the tree represent the individual entities being clustered and the internal nodes of the tree graph represent sets of entities (i.e., clusters).

Tree diagrams are particularly useful for representing nested hierarchical relationships among entities. In the world, such hierarchical relationships may come about in a number of ways. This may come about when concepts or entities may be grouped at several different levels of generality. As a specific example, people may conceptually group kinship terms into clusters of terms describing nuclear family, other lineal relatives, and collateral relatives (Rosenberg & Kim, 1975). Another way hierarchical nested relationships can come about is when evolutionary-like processes of successive differentiation result in relationships among entities that can be represented by a branching tree structure, such as in the historical development of languages (e.g., Corter, 1996, Fig. 6.1).

Tree diagrams are sometimes used to model the proximity relationships among a set of N entities, such that distances in the tree (the model distances) approximate the proximities (the observed similarities or dissimilarities) between each pair of entities. Two

distinct types of tree structures have been used to model proximity relationships: the ultrametric tree and the additive tree (Corter, 1996).

The tree in Figure 1 is an ultrametric tree. Distances in an ultrametric tree satisfy the *ultrametric inequality*, which states that for any three objects x , y , and v ,

$$d_{x,y} \leq d_{x,v} = d_{y,v}$$

if objects x and y are neighbors in the tree (relative to v). Graphically, the leaves in an ultrametric tree are all equidistant from a special point in the graph, termed the *root* of the tree. In Figure 1(a), node g is the root of the tree.

The additive tree [Figure 2(a)] is a more general structure. Distances in an additive tree satisfy the *additive inequality*, which states that for any four objects x , y , u , and v ,

$$d_{x,y} + d_{u,v} \leq d_{x,v} + d_{y,u} = d_{x,u} + d_{y,v}$$

if (x, y) and (u, v) are relative neighbors in the tree structure. Graphically, the leaves in an additive tree may be of unequal lengths. This allows the additive tree to represent entities that differ in typicality. For

Figure 2 Two Displays of an Additive Tree

example, in Figure 2, objects *B* and *C* are relatively atypical, as shown by their relatively long leaf arcs. Additive trees are sometimes represented in unrooted form, as in Figure 2(b).

TREND ANALYSIS

A prominent feature of many TIME SERIES variables is that they tend to move upward or downward over time. This tendency may be defined as a trend. Two models frequently are employed to characterize trending data. The first model is a *deterministic trend*, $Y_t = \lambda_0 + \lambda_1 T + \varepsilon_t$, where Y_t is a time series, T is time, λ_0 and λ_1 are PARAMETERS, and ε_t is a STOCHASTIC shock $\sim N(0, \sigma^2)$. If this model generates Y_t , the residuals from a REGRESSION of Y_t on T constitute a trend-stationary process.

The second model is a *stochastic trend*, $Y_t = \beta_0 + \beta_1 Y_{t-1} + \varepsilon_t$, where Y_{t-1} is the time series lagged one period, β_0 and β_1 are parameters, and ε_t is a stochastic shock. If $\beta_0 = 0$, and $\beta_1 = 1$, this model is a RANDOM WALK; otherwise, it is a random walk with drift. Recursive substitution shows that a random walk equals an initial value Y_0 , plus the sum of all shocks, $\sum \varepsilon_i$. The random walk with drift also includes $\beta_0 T$, which imparts a deterministic component to the process. First-differencing (i.e., $\Delta Y_t = Y_t - Y_{t-1}$) a random walk or random walk with drift produces a difference-stationary process.

Trending variables are *nonstationary* because they lack constant means, variances, and covariances. Regressing one nonstationary variable on another poses threats to inference (“spurious regressions”). Thus, it is vital to detect trends (nonstationarity) in time-series data. A trending series has a “characteristic

signature” when correlated with lags of itself. Several such correlations constitute an *AUTOCORRELATION function* (ACF). The ACF for a trending series has large correlations at low lags, and correlations decline slowly at longer lags. Formal statistical tests (UNIT-ROOT tests) also are widely used to detect nonstationarity.

If nonstationarity is suspected, conventional practice is to difference the data (assuming stochastic, not deterministic, trends). To determine if variables move together in the long run, COINTEGRATION tests are performed. Cointegrating variables can be modeled in ERROR correction form—for example, $\Delta Y_t = \beta_0 + \beta_1 \Delta X_t - \alpha(Y_{t-1} - \lambda X_{t-1}) + \varepsilon_t$ —where ΔY_t is first-differenced Y ; ΔX_t is first-differenced X ; $(Y_{t-1} - \lambda X_{t-1})$ is an error correction mechanism for the long-term relationship between Y and X ; ε_t is a stochastic shock; and β_0 , β_1 , α , and λ are parameters. α measures the speed with which shocks to the system are eroded by the cointegrating relationship between Y and X . α should be negatively signed and less than 1.0 in absolute value.

Differencing to ensure stationarity has been criticized on theoretical and statistical grounds. The claim is that many social science time series are either “near integrated” (β_1 in a random walk model is slightly less 1.0) or “fractionally integrated.” A fractionally integrated series possesses “long memory” and may be nonstationary. Because unit-root tests have low statistical power, they may not detect near or fractionally integrated processes. Estimating fractional differencing parameter (d) in rival ARFIMA (autoregressive, fractionally integrated, moving average) models is a useful way of considering the possibility that near or fractionally integrated processes may be operative. Recent generalizations of the concepts of cointegration and error correction permit one to model fractionally cointegrated processes.

TRIANGULATION

Triangulation refers to the use of more than one approach to the investigation of a research question in order to enhance confidence in the ensuing findings. Because much social research is founded on the use of a single research method, and as such may suffer from limitations associated with that method or from the specific application of it, triangulation offers the prospect of enhanced confidence. Triangulation is one of the several rationales for multimethod research. The term derives from surveying, where it refers to the use of a series of triangles to map out an area.

TRIANGULATION AND MEASUREMENT

The idea of triangulation is very much associated with measurement practices in social and behavioral research. An early reference to triangulation was in relation to the idea of UNOBTRUSIVE METHOD proposed by Webb, Campbell, Schwartz, and Sechrest (1966), who suggested, "Once a proposition has been confirmed by two or more independent measurement processes, the uncertainty of its interpretation is greatly reduced. The most persuasive evidence comes through a triangulation of measurement processes" (p. 3). Thus, if we devise a new survey-based measure of a concept such as emotional labor, our confidence in that measure will be greater if we can confirm the distribution and correlates of emotional labor through the use of another method, such as structured observation. Of course, the prospect is raised that the two sets of findings may be inconsistent, but as Webb et al. observed, such an occurrence underlines the problem of relying on just one measure or method. Equally, the failure for two sets of results to converge may prompt new lines of inquiry relating to either the methods concerned or the substantive area involved. A related point is that even though a triangulation exercise may yield convergent findings, we should be wary of concluding that this means that the findings are unquestionable. It may be that both sets of data are flawed.

TYPES OF TRIANGULATION

Denzin (1970) extended the idea of triangulation beyond its conventional association with research methods and designs. He distinguished four forms of triangulation:

1. *Data triangulation*, which entails gathering data through several sampling strategies so that slices of data at different times and in different social situations, as well as on a variety of people, are gathered
2. *Investigator triangulation*, which refers to the use of more than one researcher in the field to gather and interpret data
3. *Theoretical triangulation*, which refers to the use of more than one theoretical position in interpreting data
4. *Methodological triangulation*, which refers to the use of more than one method for gathering data

The fourth of these, as the preceding discussion implies, is the most common of the meanings of the term. Denzin drew a distinction between *within-method* and *between-method* triangulation. The former involves the use of varieties of the same method to investigate a research issue; for example, a self-completion questionnaire might contain two contrasting scales to measure emotional labor. Between-method triangulation involved contrasting research methods, such as a questionnaire and observation. Sometimes, this meaning of triangulation is taken to include the combined use of QUANTITATIVE RESEARCH and QUALITATIVE RESEARCH to determine how far they arrive at convergent findings. For example, a study in the United Kingdom by Hughes et al. (1997) of the consumption of "designer drinks" by young people employed both structured interviews and focus groups. The two sets of data were mutually confirming in that they showed a clear pattern of age differences in attitudes toward these types of alcoholic drinks.

Triangulation is sometimes used to refer to all instances in which two or more research methods are employed. Thus, it might be used to refer to multimethod research, in which a quantitative and a qualitative research method are combined to provide a more complete set of findings than could be arrived at through the administration of one of the methods alone. However, it can be argued that there are good reasons

for reserving the term for those specific occasions in which researchers seek to check the VALIDITY of their findings by cross-checking them with another method.

EVALUATION OF TRIANGULATION

The idea of triangulation has been criticized on several grounds. First, it is sometimes accused of subscribing to a naive REALISM that implies that there can be a single definitive account of the social world. Such realist positions have come under attack from writers aligned with CONSTRUCTIONISM and who argue that research findings should be seen as just one among many possible renditions of social life. On the other hand, writers working within a constructionist framework do not deny the potential of triangulation; instead, they depict its utility in terms of adding a sense of richness and complexity to an inquiry. As such, triangulation becomes a device for enhancing the credibility and persuasiveness of a research account. A second criticism is that triangulation assumes that sets of data deriving from different research methods can be unambiguously compared and regarded as equivalent in terms of their capacity to address a research question. Such a view fails to take account of the different social circumstances associated with the administration of different research methods, especially those associated with a between-methods approach (following Denzin's, 1970, distinction). For example, the apparent failure of findings deriving from the administration of a STRUCTURED INTERVIEW to converge with FOCUS GROUP data may have more to do with the possibility that the former taps private views as opposed to the more general ones that might be voiced in the more public arena of the focus group.

Triangulation has come to assume a variety of meanings, although the association with the combined use of two or more research methods within a strategy of convergent validity is the most common. In recent years, it has attracted some criticism for its apparent subscription to a naively realist position.

TRIMMING

A fundamental problem with the sample mean is that slight departures from normality can result in relatively poor power (e.g., Staudte & Sheather, 1990; Wilcox, 2003), a result that follows from a seminal paper by Tukey (1960). Roughly, the sample variance can be greatly inflated by even one unusually large or small value (called an OUTLIER), which in turn can result in low power when using means versus other measures of central tendency that might be used.

There are two general strategies for dealing with this problem, and each has advantages and disadvantages. The first strategy is to check for outliers, discard any that are found, and use the remaining data to compute a measure of location. The second strategy is to discard a fixed proportion of the largest and smallest observations and then average the rest. This latter strategy is called a trimmed mean, and, unlike the first strategy, empirical checks on whether there are outliers are not made.

A 10% trimmed mean is computed by removing the smallest 10% of the observations, as well as the largest 10%, and averaging the values that remain. To compute a 20% trimmed mean, remove the smallest 20%, the largest 20%, and compute the usual sample mean using the data that remain. The sample mean and the usual median are special cases that represent two extremes: no trimming and the maximum amount.

A basic issue is deciding how much to trim. In terms of achieving a low standard error relative to other measures of central tendency that might be used, Rosenberger and Gasko (1983) recommend 20% trimming, except when sample sizes are small, in which case they recommend 25% instead. This recommendation stems in part from the goal of having a relatively small standard error when sampling from a normal distribution. The median, for example, has a relatively high standard error under normality, which in turn can mean relatively low power when testing hypotheses. This recommendation is counterintuitive based on standard training, but a simple explanation can be

found in Wilcox (2001, 2003). Moreover, theory and simulations indicate that as the amount of trimming increases, known problems with means, when testing hypotheses, diminish. This is not to say that 20% is always optimal; it is not, but it is a reasonable choice for general use.

After observations are trimmed, special methods for testing hypotheses must be used (and the same is true when discarding outliers). That is, applying standard methods for means to the data that remain violates basic principles used to derive these techniques (see Wilcox, 2003).

The notion of trimming, to avoid problems with outliers and nonnormality, has been used in regression as well. For comments on the relative merits of this approach, versus other robust regression estimators that have been proposed, see Wilcox (2003).

TRUE SCORE

True score is assumed in measurement theory, which postulates that every measurement X consists of two parts: the respondent's true value or true score, and random error. That is, $X = T + e$. This concept relates to RELIABILITY. A measure with no random errors corresponds perfectly with its true score and has perfect reliability. Conversely, a measure with all random error does not correspond to any true score and has zero reliability.

—Tim Futing Liao

TRUNCATION. See CENSORING AND TRUNCATION

TRUSTWORTHINESS CRITERIA

Trustworthiness criteria provide yardsticks by which the rigor, VALIDITY, systematic nature of methods employed, and findings of qualitative studies may be judged. It is the name given to criteria appropriate to emergent, interpretive, nonpositivist, nonexperimental models of inquiry that frequently are labeled constructivist, critical theorist, action inquiry, phenomenological CASE STUDIES, or naturalistic paradigms. These criteria were the first to be proposed (Guba, 1981; Lincoln & Guba, 1985) in response to serious queries regarding the soundness, RELIABILITY, and rigor of qualitative research done under new-paradigm models.

Conventional (positivist) criteria of rigor are well established and understood: INTERNAL VALIDITY, EXTERNAL VALIDITY, reliability (replicability), and OBJECTIVITY. These four rigor domains respond, respectively, to an isomorphism to reality, to generalizability, to the stability of findings (and therefore, the ability of any given study to be replicated), and to freedom from investigator bias. Phenomenological, or new-paradigm, inquiry, however, specifically rejects each of those four domains as unachievable (in either a practical or a philosophical sense) or inappropriate (in a paradigmatic sense). It has proposed in their stead four criteria that are more responsive to both the axiomatic requirements of phenomenological inquiry and the requirements of methodologies and design strategies often more appropriate to such research, evaluation, or policy analyses, which are frequently, although not always, qualitative in nature.

Early efforts to create standards for judging non-quantitative and emergent-paradigm inquiries elicited the trustworthiness criteria: *credibility*, *transferability*, *dependability*, and *confirmability*. These criteria, deemed “trustworthiness criteria” to signal that attention to them increased confidence in the rigorousness of findings, were devised as parallel to the four criteria of conventional research. These criteria, designed as parallel to criteria for experimental models, have been criticized as “foundational,” that is, tied to a foundation emanating from conventional inquiry rather

than from characteristics inherent in phenomenological (constructivist) inquiry. Like conventional criteria for rigor, these criteria reference primarily methodological concerns; because of that, they are still highly useful when examining the methodological adequacy of case studies.

Credibility refers to the plausibility of an account (a case study): Is it believable? Is the report deemed an accurate statement by those whose LIVED EXPERIENCE is reported? *Transferability* refers to the report's ability to be utilized in (transferred to) another setting similar to that in which the original case was conducted. Judgments about transferability are unlike those about GENERALIZABILITY, however, in one important aspect. In conventional research, generalizability estimates are asserted by the researchers. In assessing transferability, however, judgments about the usefulness of results are made by "receiving contexts" (Guba & Lincoln, 1989; Lincoln & Guba, 1985), such as users and consumers of the research findings, and individuals who wish to utilize the findings in their own situations. *Dependability* references the stability, trackability, and logic of the research process employed. Dependability is assessed through a process audit, which analyzes the methodological decisions made and certifies their soundness. *Confirmability* certifies that the data reported in the case can be pursued all the way back to original data sources (e.g., FIELDNOTES, documents, records, observation logs, etc.).

Trustworthiness criteria are primarily methodological criteria; they are responsive to method (although some of the suggested methods—Guba & Lincoln, 1989—are directly tied to phenomenological premises, e.g., member checking to ascertain whether the researcher has understood the respondent's social constructions), rather than directly tied to paradigmatic assumptions. However, because new-paradigm inquiry often demands nonconventional, qualitative methods, and because trustworthiness criteria are tied heavily to the use of such methods, they continue to have applicability in judging the rigor (for instance, the level of engagement and persistence in the content) of an essential element—method—of emergent-paradigm inquiry.

T-RATIO. See T-TEST

T-STATISTIC. See T-DISTRIBUTION

T-TEST

It was William Gosset who, when performing quality controls at the Guinness brewery in Dublin, wrote articles in mathematical statistics under the pseudonym "Student." His 1908 paper "The Probable Error of a Mean" provided the basis of Student's *t*-test. The use of his Student's *t*-DISTRIBUTION in many applications is an important contribution to the analysis of small samples in mathematical statistics.

STUDENT'S T-TEST OF A SINGLE MEAN

A simple example of such an application is the test of a mean. When σ is unknown and sample size is large, we can be confident that the estimated standard error of the mean $\hat{\sigma}_{\bar{X}}$ (standard deviation of the sampling distribution of means under H_0) will be equal to the true $\sigma_{\bar{X}}$, and the ratio we will evaluate and that will be referred to as a normal sampling distribution is the standardized score $z = [\bar{X} - E(\bar{X})]/\sigma_{\bar{X}}$. However, when sample size is small, we cannot have this confidence in our estimate of the standard error; then, the ratio we use is not a *z*-score, but $t = [\bar{X} - E(\bar{X})]/\hat{\sigma}_{\bar{X}}$, in which the denominator is not a constant but a random variable, which varies along with the sample size, that is, with the DEGREES OF FREEDOM.

The *t*-distribution has a mean of 0 and a symmetric and unimodal shape, but it is flatter in the middle and denser at the extremes in comparison with the NORMAL DISTRIBUTION. As sample size *n* grows large, the distribution of *t* approaches the standardized normal distribution.

Now, suppose we hypothesize that the mean income of a particular group, say, the chemists, is larger than 2,000 euros per month ($H_a: \mu > 2,000$) as against the null hypothesis $H_0: \mu = 2,000$. The standard deviation σ is unknown. We draw a small RANDOM SAMPLE of $n = 26$. We obtain $\bar{X} = 2,040$ and $s = 100$. Our estimate of $\hat{\sigma}_{\bar{X}}$ will be

$$\frac{\hat{\sigma}}{\sqrt{n}} = \frac{s}{\sqrt{n-1}},$$

and consequently, the t -ratio is

$$t = \frac{2,040 - 2,000}{100/\sqrt{25}} = 2.$$

In the t -table, we find for a one-tailed test and $\alpha = 0.05$ a critical t -value of $t^* = 1.706$. Our sample value is higher, hence, the mean income of chemists is significantly higher than 2,000. Even in such a small sample, we obtain a significant result. However, had we performed a two-tailed test ($t^* = 2.056$), then the result would have been nonsignificant.

STUDENT'S T-TEST OF DIFFERENCE OF MEANS

Another example of application of Student's t is the t -test of DIFFERENCE OF MEANS. We can think of two groups in an experimental design, such as a group of men and a group of women, for which the scores of a QUANTITATIVE VARIABLE are considered, let us say their smoking behavior measured as the number of cigarettes per day. In this example, the dependent variable Y (smoking) is CONTINUOUS, and the independent variable X (representing the two groups) is DICHOTOMOUS. We could give the experimental group and the control group the codes $X = 1$ and $X = 2$, respectively. We want to investigate whether the mean number of cigarettes for men ($X = 1$) is significantly different from (two-tailed test) or significantly lower than (one-tailed test) the mean number of cigarettes for women ($X = 2$). The null hypothesis states that the difference of means is equal to zero. Take two groups of five individuals, that is, $n_1 = n_2 = 5$. Let the series of scores for the total sample be 2 2 3 4 4 5 6 7 8 9 with mean 5 and variation 54. The group of men with scores 2 2 3 4 4 has a mean of 3 and a variation of 4. The group of women with scores 5 6 7 8 9 has a mean of 7 and a variation of 10. The dispersions are unequal: variations 4 and 10. In order to perform a t -test legitimately, the

distributions should be approximately normal (in the case of small groups), and the variances must not be significantly different. For both conditions, there exist a couple of test procedures, the test of normality and the test of homoskedasticity (LEVENE'S TEST), respectively. Assuming that both conditions are fulfilled, the calculations are as follows.

A mean (pooled average) of the two variances is calculated:

$$\begin{aligned} s_w^2 &= \frac{\text{variation group 1} + \text{variation group 2}}{(n_1 - 1) + (n_2 - 1)} \\ &= \frac{4 + 10}{(5 - 1) + (5 - 1)} = 1.75. \end{aligned}$$

In order to obtain the sampling distribution, we consider all theoretically possible pairs of random and independent samples (with sizes n_1 and n_2) that could have been drawn from a theoretical population (i.e., a population under H_0 for which the difference in means of both samples would be zero or, at most, purely random). For each of the countless number of pairs of samples, we consider the difference of mean number of cigarettes. In this way, we obtain a sampling distribution of differences of means. The variance of such a sampling distribution appears to be equal to the sum of the variances of the two sampling distributions of means separately (one for samples with size n_1 and one for samples with size n_2). Thus,

$$\sigma_{\text{diff}}^2 = \frac{\sigma^2}{n_1} + \frac{\sigma^2}{n_2}.$$

The term σ^2 , that is, the variance of the theoretical population out of which both samples would have been drawn according to H_0 , is not known, and it is therefore estimated. The estimator used is the pooled average s_w^2 , which was calculated above. In order to use statistical tables, we apply standardization: From each difference of means, the mean of the sampling distribution of differences of means (which is equal to 0 under H_0) is subtracted, and the result is divided by the standard error σ_{diff} (which is equal to the square root of the estimated variance of the sampling distribution). Instead of classical z -scores, we obtain t -scores; the reasons for this are that the size of the sample is small, and that the variance of the population must be estimated, which results in a deviation from the normal distribution. If we now calculate the t -score for our pair of samples,

we can then situate it in the sampling distribution and come to a conclusion:

$$t = \frac{|\bar{Y}_{(1)} - \bar{Y}_{(2)}| - 0}{\left(\frac{s_w^2}{n_1} + \frac{s_w^2}{n_2}\right)^{1/2}} = \frac{|3 - 7| - 0}{\left(\frac{1.75}{5} + \frac{1.75}{5}\right)^{1/2}} = 4.78.$$

For an a priori postulated Type I error of $\alpha = 0.05$ and for $(n_1 - 1) + (n_2 - 1) = (5 - 1) + (5 - 1) = 8$ degrees of freedom, and using a one-tailed test (i.e., supposing that women smoke more than men nowadays), we find in the t -table a critical value of $t^* = 1.86$. The absolute value of t that we have calculated is higher and, consequently, has a lower than 5% probability of occurrence under the null hypothesis, that is, it is situated in the rejection region. Thus, with an a priori 95% likelihood of not being mistaken, there is a significant difference between the mean smoking behavior of women and men, with women smoking more on the average.

SOME CONSIDERATIONS

The example used here for the difference of means test is the same as in the entry on the F ratio, and the reader can verify that the F value of 22.86 obtained there is (within rounding errors) equal to the square of the t -value found of 4.78, because when the degree of freedom is one, $F = t^2$.

The null hypothesis for the test of difference between two means stated that this difference is zero. It is also possible to use some other number than zero and to hypothesize that the difference of means differs from that number.

When more than two samples are investigated, we are not allowed to make all the group comparisons by means of several t -tests; instead, we have to perform one F test. If we really want to perform multiple comparisons known as tests of contrasts, then we have to test more conservatively, that is, with lower probability of TYPE I ERROR (see ANALYSIS OF VARIANCE and related topics).

The reader should not forget that the distribution of t can be used only if the requirement that the population distribution is normal is fulfilled. This holds for the test of a single mean as well as for the test of difference of means. In most cases, we have no information on the population distribution, so this normality assumption has to be tested in the sample.

In our example, we assumed homogeneity of variances. However, this assumption can be tested by means of an F test. If this test results in a significant

difference between the variances s_1^2 and s_2^2 , then the procedure of calculating a pooled average s_w^2 of the two variances, which was used as an estimator of σ^2 , has to be replaced by a procedure in which separate standard errors are computed from each sample. The appropriate number of degrees of freedom then has to be corrected. The formula for this can be found in some statistical textbooks, such as Hays (1972) and Blalock (1972).

It should be mentioned that the two samples in our example have to be independent samples. A different procedure must be chosen when observations are paired, such as when individuals are matched in pairs by the researcher or, to take our example, when some men in Group 1 and some women in Group 2 are husband and wife. In such a case, our statement that

$$\sigma_{\text{diff}}^2 = \frac{\sigma^2}{n_1} + \frac{\sigma^2}{n_2}$$

no longer holds, but a covariance will be involved in the calculation of σ_{diff}^2 . The procedure to follow here is to look at the data as coming from one sample of pairs and to proceed with the t -test for a single mean.

A final remark is that the t -test is used in more advanced analysis, such as MULTIPLE REGRESSION for significance testing of parameters. Here, too, this t -test can be replaced by an F test, where F will be the square of t . We can also mention that Hotelling has developed a more extended version of t , Hotelling's T^2 test, which is used in DISCRIMINANT ANALYSIS for two groups and many variables.

TWENTY STATEMENTS TEST

Self and identity are two concerns of both psychology and sociology, enabling the researcher to see how people place themselves in social categories and

reflect upon who they are. The Twenty Statements Test (sometimes called the “Who am I?” test) is one of many instruments devised to measure the concept of self. It was introduced by symbolic interactionist sociologists Manford Kuhn and Thomas McPartland (1954), who wished to make George Herbert Mead’s (a leading pragmatic philosopher) concept of the self more rigorous and operational.

Subjects are asked to write down the first 20 statements that come into their mind in answer to the question “Who Am I?” They are told that there are no right or wrong answers. The test is an open-ended instrument in which answers listed can be nouns or adjectives. In their early work, Kuhn and McPartland predicted that with increasing age and with growing social change, adjectival responses (e.g., cheerful, religious, existentially aware) would be used more frequently than substantive noun responses (e.g., wife, student, man).

Theorists of self are especially interested in how ideas about self change. In traditional worlds, “pre-modern identities” may often be taken for granted. People know who they are, defining themselves through traditions and religion, with identities being shared and communal, given as part of the world. Such identities are not seen as a problem and are usually just taken for granted. By contrast, as modernity develops, human individuality and individual identity become more important. Increasingly, self-reflection upon just who one is becomes an issue. The Twenty Statements Test was meant as a research tool into such questions.

The instrument is one of a great many tools for measuring the self and is not used very much these days. Although it does allow for a broad, sweeping depiction of a sense of self, it is very basic. It has been criticized for not taking into account (a) the situated nature of the self, which changes from context to context; (b) the role of significant others in shaping what can be said; and (c) the problems of coding and content analysis, which are problems commonly associated with an open-ended questionnaire.

TWO-SIDED TEST. See TWO-TAILED TEST

TWO-STAGE LEAST SQUARES

Two-stage least squares is a procedure commonly used to estimate the PARAMETERS of a SIMULTANEOUS EQUATION model. In the face of reciprocal causation, a given in the general simultaneous equation model, where variables influence each other, ORDINARY LEAST SQUARES will yield BIASED estimates. However, two-stage least squares (TLS, or 2SLS), an INSTRUMENTAL VARIABLES method, will yield consistent parameter ESTIMATION in this situation. Suppose the following model:

$$Y_1 = b_0 + b_1 X_1 + b_2 Y_2 + e, \quad (1)$$

$$Y_2 = a_0 + a_1 Y_1 + a_2 X_2 + u. \quad (2)$$

TLS estimation goes forward in stages, and it estimates parameters an equation at a time. Let us estimate equation (1). In the first stage, all of the EXOGENOUS VARIABLES in the system (X_1 , X_2) are regressed on the independent ENDOGENOUS VARIABLE (Y_2). This creates an instrumental variable, predicted- Y_2 , which is strictly a function of the exogenous variables. In the second stage, predicted- Y_2 is substituted for observed- Y_2 in equation (1), and the equation is estimated with ordinary least squares. These second-stage estimates are consistent, because all of the INDEPENDENT VARIABLES in the equation are effectively exogenous. The same two-stage procedure is then applied to equation (2) to obtain estimates for the parameters in that equation.

TWO-TAILED TEST

A NULL HYPOTHESIS most often specifies one particular value of a population PARAMETER, even though we do not necessarily believe this value to be the true value of the parameter. In the study of the relationship between two variables, using REGRESSION analysis as an example, the null hypothesis used most often is that there is no relationship between the two variables. That translates into the null hypothesis $H_0 : \beta = 0$, where β is the SLOPE of the population regression line. Most often, we study the RELATIONSHIP between two variables for the purpose of demonstrating that a relationship does exist between the two variables. This is achieved if we are able to reject the null hypothesis of no relationship.

If we can show that the slope of the population regression line is not equal to zero—by rejecting the null hypothesis—then does the slope have a positive or negative value? If we do not have any extra information about the slope, then the alternative hypothesis becomes $H_a : \beta \neq 0$, meaning the slope can be negative or positive. Such an alternative hypothesis makes the test a *two-tailed* test, also known as a *two-sided* test.

In the original approach to this problem, as developed by Sir Ronald A. Fisher and others, they chose a preset SIGNIFICANCE LEVEL, say $\alpha = 0.05$, for lack of any better value. Depending on the nature of the analysis, they chose a test statistic, usually a z , t , CHI-SQUARE or F . For the normal z variable, 2.5% of the values are less than -1.96 and 2.5% of the values are larger than 1.96 . Thus, for the normal z variable, the null hypothesis would be rejected if the observed value of z was less than -1.96 or larger than 1.96 , meaning that the value fell in one of the two tails of the distribution.

This means that for a true null hypothesis, and repeating the study a large number of times, we would get samples, and thereby z s, 5% of the time either less than -1.96 or larger than 1.96 . For these samples, we would erroneously reject the null hypothesis. The reason for the name “two-tailed test” is that the null hypothesis is rejected for unusually large or small values of the test statistic z or t . Tests using the chi-square or the F statistic are, by their nature, set up to be two-tailed tests.

With the arrival of statistical software for the analysis of the data, there has been a shift away from the significance level α , chosen before the analysis, to

the use of P VALUES, computed as part of the analysis. For z and t , if we see the absolute value symbol $|z|$ or $|t|$, then the corresponding p values represent two-tailed tests. If we decided before starting the analysis to make use of a two-tailed test, and the software provides a one-tailed p value, then we have to double this p value.

It is also possible to simply report the computed p value and let the reader determine whether the test should be two-tailed or one-tailed.

TWO-WAY ANOVA

Two-way analysis of variance (two-way ANOVA) is the test used to analyze the DATA from a study in which the investigator wishes to examine both the separate and the combined effects of two VARIABLES on some measure of behavior. The data come from a factorial experiment or study in which separate levels of each of two variables or factors (e.g., Factor A and Factor B) are identified and all combinations are formed. Factors A and B may be manipulated INDEPENDENT VARIABLES, such as incentive level or performing alone versus in groups, or measured levels of subject variables, such as age and sex. Among the more interesting applications in the social sciences are ones in which Factor A is a manipulated independent variable and Factor B is a subject variable. The primary interest is then whether the effect of Factor A on the response measure differs for individuals defined by different levels of Factor B.

Consider, for example, a study of the effects of exposure to violent video games on subsequent aggressive behavior exhibited by young boys and girls. Let's say that the behavior being recorded—the DEPENDENT VARIABLE—is the number of times a child hits, kicks, or pushes another child during a 15-minute play session. Using a population of children of a certain age (say, 6 to 7 years old), children are randomly

Table 1 Case of Significant Main Effects and No Significant Interaction

Source	DF	SS	MS	F	p
Gender	1	122.51	122.51	33.56	<.0001
Game	1	103.51	103.51	28.35	<.0001
Gender $\times$ Game	1	1.01	1.01	0.28	.600

assigned to a condition where they play a 30-minute violent video game or a 30-minute nonviolent video game before the play session with other children. This constitutes the independent variable manipulation. This RANDOM ASSIGNMENT is done separately for boys and girls, resulting in a 2×2 design with two levels of type of video game crossed with two levels of gender.

The resulting data and two-way ANOVA then can be used to address the following research questions: (a) Are boys more aggressive than girls? (b) Are children more aggressive following experience with a violent video game? and (c) Do boys and girls differ in the effect of exposure to violent video games? In ANOVA parlance, the first two questions are addressed by MAIN EFFECT tests—that is, averaged over experimental conditions, are the mean aggression scores significantly higher for boys than for girls, and, averaged over gender, are the mean aggression scores significantly higher in the Violent Video Game condition than in the Nonviolent Video Game condition? The third question, which is probably the one of greatest interest, is addressed by a test of INTERACTION—does the effect of exposure to violent

Table 2 Case of Significant Main Effects and Significant Interaction

Gender $\times$ Game	1	37.81	37.81	13.93	<.0004

video games differ significantly between boys and girls?

DISPLAYING THE RESULTS

These three tests—the two main effects and the interaction—are independent of each other in a two-way ANOVA, meaning that any combination of significant and nonsignificant results is possible (see Hays, 1994; Jaccard, 1998; and Levin, 1999, for computational procedures). An ANOVA table, coupled with a graph of the mean results for each combination of Factors A and B, gives the complete picture. A couple of interesting sets of hypothetical results are illustrated above. In the first example, the ANOVA table shows that both main effects are significant, whereas the interaction is not (see Table 1). The graph, showing approximately parallel lines for boys and girls, illustrates that boys are more aggressive than girls, but that children of both sexes show comparable increases in aggression following exposure to a violent video game compared to a nonviolent video game (see Figure 1). In the second example, both main effects are again significant, but so is the interaction (see Table 2).

**Figure 1** Aggressive Behavior as a Function of Gender and Video Game Type**Figure 2** Aggressive Behavior as a Function of Gender and Video Game Type

The accompanying graph shows that boys are much more strongly influenced by exposure to violent video games than are girls, as illustrated by the greater separation of lines for the Violent condition than for the Nonviolent condition (see Figure 2). Detecting and describing the interaction is what enables us to distinguish between these two sets of results. The use of two-way ANOVA in conjunction with a factorial study allows the researcher to investigate the separate and combined effects of two variables in a single study. The same principle can be extended to three-way ANOVA with three variables, and so forth.

TYPE I ERROR

Type I and Type II errors are errors that can occur with HYPOTHESIS TESTING. Even though data are available only for a RANDOM SAMPLING of observations and not on the entire POPULATION, the sample data can be used to draw conclusions about the larger population. This means extrapolation from the small sample to the large population, and therefore, we may make errors. The two main types of errors are called errors of Type I and Type II.

The extrapolation from sample to population is done by setting up a NULL HYPOTHESIS. There, we specify one or more values for a population parameter. These are examples of null hypotheses: $H_0 : \mu = 100$ (the population MEAN equals 100), $H_0 : \sigma^2 \geq 25$ (the population VARIANCE is equal to or greater than 25), $H_0 : \beta = 0$ (the population REGRESSION COEFFICIENT equals 0). We want to learn about the values of the population parameters, but because the values are not known, a null hypothesis becomes more of a question. For the first null hypothesis, could it be that the population mean equals 100?

Consider the case where the null hypothesis really is true. If the sample data are such that we reject the null hypothesis and conclude that it is not true, then we have made a mistake. Because the null hypothesis really is true, it should not have been rejected. This is a Type I error—rejecting a null hypothesis even though it really is true.

We will never know whether we commit this error or not, because the true value of the population parameter remains forever unknown. All we do here is examine what happens when the null hypothesis is true and we have data that lead us to reject the null hypothesis. It is possible to speculate on how often we will make such a Type I error. Suppose, over a lifetime, we examine 1,000 different null hypotheses, where 800 of them are false and 200 are true. If we commit the error of Type I 5% of the time, we will have made this error in 10 of the 200 true cases (10 of 200 is 5%). The 800 other null hypotheses are irrelevant here, because we deal only with those null hypotheses that are true.

To decide whether we reject a null hypothesis or not, we use the sample data to compute the so-called P VALUE. Most statistical software will compute this number for us. It tells us, in the case where the null hypothesis is true, how often we get our sample data or more extreme data. For example, let $H_0 : \beta = 0$, and from the data, $b = 4.56$ with $p = .001$. Thus, if the population regression line is truly horizontal (there is no relationship between the two variables), we will get a sample regression coefficient of 4.56 or larger only one time in 1,000 replications of this study.

TYPE II ERROR

STATISTICAL INFERENCE methods are used to draw conclusions about values of unknown PARAMETERS. In HYPOTHESIS TESTING, a NULL HYPOTHESIS is set up specifying one or more values of the parameters: $H_0 : \mu = 100$ (the population MEAN equals 100),

$H_0 : \sigma^2 \geq 25$ (the population VARIANCE is equal to or greater than 25), or $H_0 : \beta = 0$ (the population REGRESSION COEFFICIENT equals 0). Because the parameter values are unknown, a null hypothesis becomes a statement about possible values of the parameters. It is as if we are asking whether the parameters could have the values specified in the null hypotheses.

SAMPLE data are used to answer questions posed in the null hypotheses. Based on the data, we make decisions about whether to reject or not reject the null hypothesis. Because such a decision is an extrapolation from the limited sample data to a larger population, it is possible to make errors. If the actual value of the parameter is the value specified in the null hypothesis, then the null hypothesis is true. If we still reject the null hypothesis, we make a TYPE I ERROR.

It may be, however, that the actual value of the parameter is not equal to the value specified in the null hypothesis. In that case, the null hypothesis is false and should be rejected. But if the data are such that we fail to catch the fact that the null hypothesis is false, then we have made an error. This is a Type II error—not rejecting a false null hypothesis.

Whether such an error is committed depends on two things. First, it depends on how far the true value of the parameter is from the value specified in the null hypothesis. If the true population mean $\mu = 101$, and the null hypothesis states that the population mean $\mu = 100$, then the null hypothesis is false and should

be rejected. But with such a small difference between the two, it will be very difficult to discover that the null hypothesis is false. In many replications of the study, the sample means will cluster around 101 rather than 100. However, this difference may be so small that it does not matter for the problem at hand.

Second, whether the data will detect that the null hypothesis is false will depend on how many observations there are in the sample. With small samples, it is more difficult to discover that a null hypothesis is false than it is with large samples. With large samples, the sample statistic in replications of the study will cluster more tightly around the true parameter value, and we reject the null hypothesis more often. For a fixed value of the parameter and a given sample size, we can compute how often (the PROBABILITY) we will get data such that the null hypothesis is erroneously rejected. The *power* of the test is defined as one minus this probability.

U

UNBALANCED DESIGNS

Unbalanced designs (sometimes called nonorthogonal designs) are FACTORIAL research designs in which QUALITATIVE INDEPENDENT VARIABLES are correlated. This circumstance, akin to MULTICOLLINEARITY in REGRESSION analysis, makes impossible the unambiguous estimation of the correlated independent variables' effects. As a rule, designs are unbalanced when sample sizes are unequal—that is, when the numbers of subjects per cell differ. A special case occurs when one cell is entirely empty.

Yates (1934) showed that in analyzing data from an unbalanced design, ordinary ANALYSIS OF VARIANCE (ANOVA) will, for most purposes, be misleading. Using Type I sums of squares (SS), ANOVA assigns explanatory weight to an independent variable partly on the basis of that variable's sequence in the model. The first variable captures all of the variance confounded with it, whether that variance is unique or is shared with one or more other independent variables. The independent variable that follows the first will be given weight only to the extent that it adds an additional increment to the explained SS, and so on with subsequent variables.

To address this arbitrary feature of Type I SS, Yates developed a method called weighted squares of means, now generally known as Type III SS, which has become the routine analytic choice with unbalanced data. In that method, SS are assigned to each independent variable as if it were the last variable in a Type I model; that is, a variable's weight is determined by its unique contribution to the explanation after all other factors

have been taken into account. Thus, an independent variable's SS is in fact its partial SS. Note that the SS associated with the confounded independent variables is left unassigned here.

Nelder and Lane (1995) find this approach unrealistic, arguing that it may, among other things, produce models with INTERACTIONS but lacking the corresponding MAIN EFFECTS. In its place, they propose the use of Type II analysis (also known as Yates's method of fitting constants). The Type II method involves adjustment for the other factors only if those factors do not include the variable being estimated. Thus, X_1 would not be adjusted for $X_1 \cdot X_2$ because the latter contains the former. When a model includes only main effects, Type II analysis is no different from Type III. In other cases, Type II requires choices about which factors to drop from the model to proceed.

When one or more cells in a factorial model are empty, the results from Type I, II, or III analysis often defy interpretation. A fourth method, more technically complex, is available. Type IV SS involves constructing a hypothetical, balanced data cell matrix that then is used as the basis for estimating effects. The solution may not be unique, and for that reason and others, great caution is urged in its interpretation.

—Douglas Madsen

UNBIASED

An ESTIMATOR is said to be unbiased when the expected value of the estimate $\hat{\beta}$ equals the true value of the PARAMETER β : $E(\hat{\beta}) = \beta$. Unbiasedness is a desirable property for an estimator because it provides confidence that our estimates of a parameter, on average, equal the true parameter. An estimate is biased when the expected value of the parameter does not equal the true value $E(\hat{\beta}) \neq \beta$. The BIAS can be calculated by subtracting the true value of the parameter from the expected value of the estimate: $\text{bias} = E(\hat{\beta}) - \beta$.

One way to think of unbiased estimators is by imagining two people shooting a bow and arrow and trying to hit the center of a target. Each person is a different estimator, and the center of the target represents the true value of the parameter being estimated. Person 1 shoots 100 arrows; the average arrow shot hits the center of the target. Person 2 shoots 100 arrows. However, Person 2's aim is not as good, and the arrows go slightly to the left. The average arrow shot by Person 2 is about 1 foot to the left of the center. The average locations of the arrows represent the expected values of the estimates generated by the two estimators. Person 1 would be an unbiased estimator because, on average, he or she was able to hit the center. Person 2 would be a biased estimator because the average arrow went to the left of the true value.

It should be noted that unbiasedness is a property of the PROBABILITY DISTRIBUTION generating the estimates. An unbiased estimating technique will not give us the true value of our parameter on each try. Rather, it is only after repeated SAMPLING that the average value of the estimated parameter is equal to the true value of the parameter.

Just because an estimator is unbiased does not mean that it is the ideal estimator (Wooldridge, 2002). Rather, an unbiased estimator does us little good if it is not an efficient estimator (see EFFICIENCY). An inefficient estimator's probability distribution has a large variance, causing high uncertainty in the probability of any given estimate equaling the true value of the parameter.

Occasionally, we will use estimators that are biased because they have other desirable properties.

Unbiasedness is an attractive feature of ORDINARY LEAST SQUARES (OLS) as an estimation technique. Wooldridge (2002) explains that OLS is unbiased when four conditions are met. First, the relationship between the dependent and independent variables is LINEAR in functional form. Second, the observations are drawn from a RANDOM SAMPLE. Third is the ASSUMPTION of zero conditional mean. Zero conditional mean states that, given x , the expected value of the errors is zero. Fourth, there is variation in the variables being studied. When these conditions are met, OLS is an unbiased estimator. When an estimator is shown to be efficient, has a minimum variance, and is unbiased, it is a special class of estimator called a BEST LINEAR UNBIASED ESTIMATOR (BLUE).

UNCERTAINTY

Social scientists are doubly concerned with uncertainty: Formal research methods are designed to quantify the uncertainty that arises when building THEORIES of an imperfectly predictable social world. But much of the variability in human behavior that demands these methods is generated by the judgments that individual society members make in light of their own uncertainty.

Rational expectations theories in economics are a rare case when the two concerns are explicitly related: The price of a stock, a society-level phenomenon, is predicted to evolve randomly over time because all the available systematic information will have been used by individual investors to minimize their uncertainty about its value. Any remaining price movement reflects residual investor uncertainty.

PROBABILITY provides the basis for addressing both concerns with uncertainty: Most economic and political theory assumes that probabilistic inference is a reasonable BEHAVIORAL model of individual decision making in an uncertain world. Uncertainty about

particular social scientific theories is also expressed using probabilities and the associated machinery of STATISTICS. But probability is not the only possible choice for quantifying uncertainty, so it is worth considering why it is a good one.

There are several arguments motivating individuals to use probability theory for managing their uncertainty. “Dutch Book” arguments show that individuals who act on their uncertainty in a way that is inconsistent with probability theory can, in gambling situations, always be fleeced (Ramsey, 1960). A more general motivation for probability was provided by Richard Cox (1946/1990). Cox showed that for any numerical measure of certainty, plausibility, or confidence in a Proposition A that we might invent, it must be a simple rescaling of the probability that A is true if it has the following intuitive properties:

1. Transitivity: If A is more plausible than B, and B is more plausible than C, then A is more plausible than C.
2. The plausibility of A is a function of the plausibility of not-A. (For example, the more plausible A is, the less plausible not-A is.)
3. The plausibility of A and B together is a function of the plausibility of A, as well as the plausibility of B when A is certain.

If these properties apply to the measure, then the number we assign to A will be a constant multiple of the probability of A. If Principles 1 through 3 are accepted as minimum requirements, then probability theory is the correct way to quantify uncertainty. Since Cox’s argument does not depend on whether the uncertainty being quantified is personal or social scientific, it provides a general motivation for quantifying uncertainty with probability. Despite the wide application of rational expectations theories in economics, most psychologists doubt that probability theory is a good descriptive model of individual reasoning under uncertainty (Tversky & Kahneman, 1974). For example, people are overconfident relative to available data and partially neglect the prior probability of events when they make predictions (base-rate neglect). These psychological facts are not necessarily problematic for rational expectations theories because individual expectations need only be consistent with probability theory on average. Nor do they prevent probability-based theories of personal inference; people may be making a probabilistically correct inference on an

incorrect internal model or taking into account causal constraints (Cheng, 1997). People also seem to process information in a way that trades some of the advantages of probabilistically correct INFERENCE for speed by using an incorrect but less computationally demanding inference process that is only approximately correct (Gigerenzer & Goldstein, 1996).

The question of whether scientific uncertainty should be quantified in the same way as personal uncertainty defines the debate in statistics between frequentists and BAYESIANS. We focus on this question with two interpretations of a familiar example.

A LINEAR REGRESSION model of the relationship between some quantity Y and two potentially explanatory variables X_1 and X_2 can be written as

$$Y = X_1b_1 + X_2b_2 + e$$

$$e \sim \text{Normal}(0, \sigma^2). \quad (1)$$

In a Bayesian treatment of this model, parameter values are uncertain, and this uncertainty is described by a PRIOR PROBABILITY distribution, $p(b_1, b_2, \sigma^2)$. But even if the parameters were known with certainty, the outcome Y would be uncertain. This uncertainty is factored into a DETERMINISTIC part, the additive relation $X_1b_1 + X_2b_2$, and a STOCHASTIC part by assuming a particular probability distribution for the RANDOM VARIABLE e . Uncertainty about Y can be partly reduced by observing values of X_1 and X_2 , down to the minimum level determined by e ; e may represent the work of a truly random social process or our belief that there are variables relevant to Y not included in the model. Equation (1) defines a distribution over outcomes $p(Y|b_1, b_2, \sigma^2)$ that is conditional on particular values of the PARAMETERS and explanatory variables (ignoring the known explanatory variables). BAYES THEOREM combines these two distributions into a posterior probability distribution, $p(b_1, b_2, \sigma^2|Y)$. The posterior probability distribution combines uncertainty about parameter values and uncertainty about the value of Y that would persist even if everything else were known. The peak of the posterior is the most probable value for the parameters, and a 95% interval has a 0.95 probability of containing the true value.

The posterior distribution is conditional on Y because after the data are observed, their values are known with certainty. Conditioning on the observed data is only possible because there is a prior distribution. For frequentists, it is inappropriate to use prior distributions in science because it reduces the objectivity

of scientific inference. In this case, probability is restricted to describing objectively random mechanisms, and uncertainty is confined to states of complete ignorance. Under this interpretation, e describes an objective physically or socially random process, and the parameters are fixed but completely unknown.

To infer values for the parameters, frequentists choose a function of the available Y values to be an ESTIMATOR and then compute a POINT ESTIMATE and CONFIDENCE INTERVAL. Because Y has a probability distribution in virtue of containing e , parameter estimates (but not the parameters themselves) also have a distribution because they are functions of the objectively random Y . Confidence intervals reflect uncertainty by using probability only indirectly: It is the method of interval construction that is associated with a probability of, say, 0.95 in the sense that in repeated sampling, 95% of intervals constructed this way would contain the true parameter value. Because observed Y values cannot be conditioned on, a confidence interval depends on infinite numbers of hypothetical outcomes—values of Y that did not actually occur but could have done.

Although a definition of probability in terms of repeated samples allows frequentists to avoid quantifying levels of uncertainty, it can be problematic. For example, much social science research is concerned with explaining essentially unique situations in which the idea of a repeat sample may not make sense. In contrast, interpreting e as an uncertainty measure is consistent with any position on the possibility of repeated sampling because there will be uncertainty about outcomes in either case.

As for the uncertainty represented by priors over parameters, it is important to see that a posterior distribution states what it would be rational to believe on the basis of observed data given a set of prior beliefs. Given a different set, the rational beliefs might well be different. Although the prior is inevitably subjective, it is also explicitly represented and introduces no ambiguity into inference, and the consequences of changing it may be informative about the information content of the data.

The debate between frequentists and Bayesians about social scientific inference turns on whether probability is always the best representation of uncertainty—in other words, whether the benefits of being able to condition on data that are actually observed, removing sampling theoretic constraints

and being consistent with foundational arguments for probability as a measure of uncertainty should outweigh concerns about introducing subjective elements into the process of increasing scientific knowledge about the social world.

UNIFORM ASSOCIATION. See
ASSOCIATION MODEL

UNIMODAL DISTRIBUTION

This is a DISTRIBUTION of values for a single VARIABLE that only has one mode and a single “peak.” The mode is one of three common measures that are used to determine a variable’s “typical score” and is the most frequently occurring value of any given variable (Lewis-Beck, 1995, p. 8).

An example of a unimodal distribution is the standard NORMAL DISTRIBUTION. This distribution has a MEAN of zero and a STANDARD DEVIATION of 1. In this particular case, the mean is equal to the MEDIAN and mode. Moreover, the standard normal distribution

Figure 1 Histogram for Household Income at Selected Percentiles

only has a single, equal mean, median, and mode. Therefore, it is a unimodal distribution because it only has one mode.

However, a unimodal distribution does not have to have SYMMETRY like the standard normal distribution. A unimodal distribution can also be SKEWED to the left or right. An example of such a distribution is that of income in the United States.

Figure 1 illustrates the annual income of the U.S. population by different categories (DeNavas-Walt & Cleveland, 2002, p. 20). The MEDIAN income, in which half of the values are greater and half are smaller, falls in the \$42,228 category. This figure suggests that the distribution of American household income is somewhat skewed to the left because the median is closer to the bottom 10% (at \$10,913) than to the top 10% of all households (at \$150,499). Furthermore, the modal category is \$42,228. There is a much larger percentage of households (about 50%) in this income category than in the other income categories, indicating the distribution is clearly unimodal.

Regardless of whether a unimodal distribution is skewed or symmetric, it must have a single “peak.” A distribution with a single “peak” is one in which there is a single most frequently occurring value of any given variable, as illustrated by its FREQUENCY DISTRIBUTION. If a distribution has two “peaks,” then it is a BIMODAL DISTRIBUTION. Finally, if a distribution

has more than two “peaks,” then it is a MULTIMODAL DISTRIBUTION.

UNIT OF ANALYSIS

A unit of analysis is the most basic element of a scientific research project. That is, it is the subject (the who or what) of study about which an analyst may generalize. In the social sciences, countries, international alliances, schools, communities, interest groups, and voters are often the units of analysis in studies of economic development, war, teaching strategies, social capital, policy outcomes, and vote choice.

Units of analysis may be different from the units of observation. For example, political scientists may aggregate survey data at the country level by estimating the mean score on an item measuring political participation, assigning that same score to the country to identify how patterns of participation differ cross-nationally. In this case, the unit of observation is the individual survey respondent, but the unit of analysis is the country. Likewise, achievements of students are often aggregated to allow schools to be compared. It is the country and the school about which the analyst generalizes, not the citizens or students (see AGGREGATION for a word of caution).

In these examples, more detailed information is available than the analyst requires for his or her project. Often in the social sciences, however, this is not the case: Researchers frequently examine the behavior of units that are unobserved. For example, following Achen and Shively (1995), an analyst may wish to examine the relationship between a social attribute and voting behavior but has only data aggregated at the district level available. That is, he or she has the proportions of those living in the district who have this attribute and of those supporting the party. If both

proportions are large, the analyst is tempted to infer that there is an association between these variables at the level of the individual: Voters with this attribute are likely to vote for the party. This type of cross-level inference, in which the unit of analysis does not coincide with the unit of observation, is misleading and should be approached with caution (see ECOLOGICAL FALLACY).

Even when units of analysis match the units of observation, however, the characteristics of social units complicate scientific inference. Boucke (1923) notes two differences that distinguish social units from the units of analysis common in the natural sciences: First, the units of social science research are not measurable in a straightforward way or on a determinate scale. Often, a considerable proportion of variance in social phenomena can be attributed to measurement error (see SYSTEMATIC ERROR). Also, some units of interest may be observable only in their causal implications (see Blalock, 1961). Second, as evident in the examples presented above, units of analysis in the social sciences can usually be divided into various subunits: Communities may be divided into families or households, geographic neighborhoods, or individual members. Boucke concludes that units of analysis in social science are not “things” but the relationships or networks connecting the families, neighbors, or, at the most basic level, the interests of individuals. Subunits rarely have the potential for such substantive meaning or CONFOUNDING effects in the natural sciences. Furthermore, the variability of relations between subunits makes scientific inference a difficult task: The composite nature of the units of analysis in social research makes “predictions risky, and the more so, the more fully they concern psychic rather than material relations” (Boucke, 1923, p. 460). Analysts working in the social sciences would do well to accommodate these implications of their choice of unit of analysis in their research designs.

UNIT ROOT

A times series can be modeled as a function of its own past, that is, as an autoregression. In its simplest form, such a series is written as

$$y_t = \alpha + \beta y_{t-1} + \varepsilon_t,$$

where the ε_t s are assumed to be independent of each other. This series has a unit root if $\beta = 1$. The presence of a unit root has critical consequences for interpretation and ESTIMATION, both for the simple autoregression and for a more complex model with a lagged dependent variable and other independent variables. It is critical to test for whether an autoregressive series has a unit root and, if so, to take account of this in estimating the model parameters.

If a series has a unit root, then we can rewrite the autoregressive form as $y_t = \alpha + \varepsilon_t + \varepsilon_{t-1} + \varepsilon_{t-2} + \dots$, so that current y is the sum of all previous errors. (Integration is just a form of summation, which is why such a series is called “integrated.”) Because the errors are independent, the variance of y grows larger over time. Thus, all the usual assumptions that make the asymptotic theory of REGRESSION work no longer hold and all standard methods are incorrect. In particular, if the autoregressive series has a unit root, but we try to estimate β by ORDINARY LEAST SQUARES, we will underestimate β and misestimate its standard error. Interpretation is also dramatically affected: With a unit root, small perturbations of a series will persist forever rather than die out, as would happen with a stationary series (where $|\beta| < 1$). The CENTRAL LIMIT THEOREM does not even hold for integrated series, and so all standard distribution theory breaks down in this case.

Dickey and Fuller were the first to design a correct test for the null hypothesis that a time series has a unit root. This consists of using ordinary least squares to estimate β and then forming the Dickey-Fuller statistic $(1 - b)/SE$, where b is the ordinary least squares estimate of β and SE is the ordinary least squares standard error of this estimate. With a stationary time series, this statistic has a τ -DISTRIBUTION; under the null hypothesis of a unit root, Dickey and Fuller had to use deep mathematics to derive the appropriate distribution of the statistic. Thus, users compute the Dickey-Fuller statistic and compare its value to the

distribution tabulated by Dickey and Fuller. There are many modern improvements on this test, but they are all based on the original idea of Dickey and Fuller. When using the Dickey-Fuller test, it is important to remember that the null hypothesis is that the series is integrated. If this null hypothesis is rejected, then standard methods can be used. If it is not rejected, this does not mean that the series has a unit root—it only means that we do not have enough information to reject this hypothesis. Unfortunately, there is no test that reverses this logic, so researchers typically assume a unit root if the Dickey-Fuller test fails to reject this hypothesis.

If a series has a unit root, then standard ordinary least squares methods cannot be used. One solution is to take first differences and model those because the first differences will usually not show a unit root. Substantively, this is equivalent to modeling only the short-run behavior of a series, ignoring any long-run behavior of that series. Alternatively, analysts faced with a unit root can use the methodology of COINTEGRATION.

UNIVARIATE ANALYSIS

Univariate analysis is the analysis of the statistical characteristics of a single VARIABLE, including its DISTRIBUTION, its CENTRAL TENDENCY, and its SPREAD.

The first step in univariate analysis is to plot the observations in a table or graph to examine the variable's distribution. NOMINAL variables can be presented in a PIE CHART or BAR chart. In a pie chart, each wedge in a pie represents a category of the variable. In a bar chart, the height of each bar represents the number or proportion of observations in each corresponding category of the variable. INTERVAL and RATIO data are often presented in a HISTOGRAM, BOXPLOT, or QUANTILE plot. Some variables have SYMMETRIC distributions, whereas other variables have SKEWED

distributions with OUTLIERS that can distort STATISTICS that are calculated on them.

Summary statistics for a single variable are often called DESCRIPTIVE STATISTICS. Central tendency measures summarize the typical value of the variable. The arithmetic average, known as the MEAN, is usually used as a measure of central tendency for numeric variables. The MEDIAN—the value of the variable for the middle ordered observation—is used for ORDINAL variables. The MODE—the value that occurs most often—is used for nominal data. The median is often used in place of the mean for numeric data when there are outliers in the data or when the variable's distribution is extremely skewed.

Measures of DISPERSION indicate the amount of variation in a variable's observations. For nominal or ordinal data, crude measures of dispersion include the number of categories and the number of observations in the modal category. For numerical variables, the simplest measure of dispersion is the RANGE, the difference between the highest and lowest observation. Because outliers can distort the range, an alternative is the INTERQUARTILE RANGE, the difference between the 25th percentile and the 75th percentile. The interquartile range is prominently featured in boxplots. For interval and ratio data, the STANDARD DEVIATION and VARIANCE (the square of the standard deviation) are common measures of dispersion. Larger values of the standard deviation and variance indicate more dispersion among the observations.

The distribution of a single variable can also be examined to determine how closely it approximates a symmetrical, bell-shaped NORMAL DISTRIBUTION. Symmetrical distributions have the same shape on either side of the median. Skewness statistics indicate how much a distribution deviates from being symmetrical. The KURTOSIS statistic indicates the extent to which a distribution has a tall, thin peak or a short, flat peak around the mode.

UNIVERSE. See POPULATION

UNOBSERVED HETEROGENEITY

Unobserved heterogeneity refers to latent or hidden characteristics of observations. These characteristics are properties of individuals or subgroups that cannot be measured or are left unmeasured in a study. Ordinarily, individual or group characteristics are incorporated into statistical models as COVARIATES (or INDEPENDENT VARIABLES). When unmeasured characteristics affect the process under investigation, unobserved heterogeneity among observations is said to exist.

For some statistical models, failure to account for heterogeneity among individuals or groups can lead to BIASED PARAMETER ESTIMATES, misinterpretation of results, or SPURIOUS time-covariate interactions. Consequently, statistical techniques have been developed that explicitly incorporate unmeasured heterogeneity as the component of a model. The result is one or more additional parameters that describe how the unmeasured characteristics are distributed in the population from which the sample was drawn.

AN EXAMPLE

Consider the ages at marriage in a rural area of Bangladesh (Figure 1). The heavy line shows the distribution that arises when gender is not considered (or left unmeasured). Suppose a lognormal distribution is believed to be a proper model for age at marriage. Fitting the observations to a lognormal distribution (without reference to sex) yields parameters that give a MEAN age (STANDARD DEVIATION) of 23.3 (5.9) years. Failure to consider gender masks substantial subgroup differences. In fact, a gender-specific analysis yields a mean age of marriage of 27.3 (5.5) years for males and 19.5 (3.4) years for females. The subgroup differences are so large that parameter estimates for any other measured covariate (say, the effect of education on age at marriage) are likely to be BIASED by the lack of information on gender.

Figure 1 Ages at Marriage in Matlab, Bangladesh, in 1985

SOURCE: Data are from the International Centre for Diarrhoeal Disease Research, Bangladesh (1992).

With no information on gender, one solution is to estimate parameters for a finite mixture model. A four-parameter mixture model can be estimated assuming equal numbers of males and females and yields estimates of 25.4 (7.1) years for one subgroup and 21.4 (4.0) years for a second subgroup. The subgroups correspond to males and females, respectively.

“DEVIOUS DYNAMICS” IN HAZARDS MODELS

Failure to account for unobserved heterogeneity can lead to serious problems of interpretation for survival analysis and related methods that deal with durations to events (hazards models or EVENT HISTORY models). For these models, unobserved heterogeneity refers to unmeasured differences among the units of observation in their risk of “failure” (i.e., risk of experiencing the event under investigation). Ignoring unmeasured heterogeneity in risk of failure leads to a downward bias in risk with time.

Consider mortality risk in infants, which is initially very high and declines rapidly over the first years of life. Taken literally, this observation implies that infants undergo reverse senescence: Individuals “get better” with age. In part, this pattern reflects known biological processes such as maturation of the immune system. On the other hand, the same “infant mortality” pattern is seen for other complex systems such as computers and automobiles—it is less plausible to believe

Figure 2 A Mixture of Two Homogeneous Subgroups, Each at a Constant Hazard (or Risk) of Failure

NOTE: Risk appears to decline with age when the subgroups are combined.

that individual computers experience a decline in risk of failure during early service. The apparent reverse senescence is an artifact of the changing composition of the sample over time, a product of the “devi-ous dynamics of aging cohorts” (Vaupel & Yashin, 1985a, 1985b).

Figure 2 shows how aggregate risk is biased downward with time as a result of unobserved heterogeneity. Two subgroups are shown, one at a high and constant risk of failure and a second at low and constant risk of failure. The subgroups initially contain the same number of individuals. When the subgroups are combined and treated as a single homogeneous population, a decline in risk of failure is observed with age. This decline occurs because individuals in the high-risk subgroup are failing at a higher rate. Over time, the surviving population is increasingly made up of low-risk individuals.

An important special case of heterogeneity arises when all individuals in one of the latent subgroups are not at risk of failure. For example, a demographer studying fecundability in couples might observe times from marriage until each couple’s first birth. Some fraction of the couples may be sterile and will therefore never give birth. Difficulties arise when some of the fecund couples drop out of the study or are lost to follow-up before their first child is born (i.e., they are right censored; see CENSORING). Those couples whose first birth is not observed come from two fundamentally different subgroups: the right-censored fecund individuals and the sterile individuals. Special

analytical models—called sterility models, immune models, or mover-stayer models—can be used to estimate an unbiased distribution of waiting times to first birth and the initial fraction of sterile individuals. This type of process arises in many social sciences contexts, including studies of marriage, divorce, birth spacing, recidivism, occupational mobility, and residential mobility.

FRAILTY MODELS

Unobserved heterogeneity in risk of failure can be distributed among individuals in a way that approximates a continuous distribution. An important illustration is the concept of *frailty* that developed out of demographic studies of mortality (Vaupel, Manton, & Stallard, 1979). Individuals have unmeasurable (or unmeasured) genetic, environmental, or behavioral liabilities or *frailties* that uniquely modify their risk of mortality from some baseline distribution. An individual frailty is described by the quantity z_i , but because z_i is not measurable, an alternative is to estimate parameters for a probability distribution that describes how z is distributed among individuals.

For many types of frailty models, the effect of z on the hazard of failure is specified as a proportional hazards model, so $h(t|z) = h(t)z$ for time t . The frailty distribution is selected to have a mean of 1; a variance parameter is estimated and describes the way frailty is distributed in the population. The most commonly used parametric frailty distribution is the gamma distribution. Occasionally, the specification $h(t|z) = h(t)e^z$ is used when the distribution of z has a mean of zero; the NORMAL DISTRIBUTION is frequently employed.

Results from a frailty model can be sensitive to the choice of frailty distribution. An alternative approach specifies the distribution of heterogeneity as a piecewise discrete density function (Heckman & Singer, 1982). The number and location of mass points are determined empirically. This approach may be particularly appropriate when theory does not suggest an appropriate distribution for z . Even so, this strategy can be sensitive to the parametric model used for the hazard function (see Trussell & Rodríguez, 1990).

In addition to frailty models, there are many other commonly used parametric models of unobserved heterogeneity. For example, the BINOMIAL and GEOMETRIC distributions can incorporate a distribution of heterogeneity for the probability (p) of the event under investigation. A beta distribution is frequently used as

the distribution of p , if only because the range of the distribution lies from 0 to 1.

UNOBTUSIVE MEASURES

Unobtrusive measures is the title of the classic reference for unobtrusive research procedures by Webb, Campbell, Schwartz, and Sechrest (1966; see also the revised edition by Webb, Campbell, Schwartz, Sechrest, & Grove, 1981). An excellent summary has also been published by Lee (2000); see also UNOBTUSIVE METHODS. Instead of *measures*, the more inclusive term *unobtrusive methods* is now more frequently used because it includes methods other than the quantitative ones focused on by Webb et al.

“Unobtrusive measures” are research procedures designed to avoid a major problem in much social science research, namely, REACTIVITY (Webb et al., 1966). Research participants typically “react” to their situation; that is, they perceive or suspect that they are being observed or evaluated in some fashion. If one measures length with a ruler, the measurement process does not affect the accuracy or validity of the observation. If, however, attitudes about an issue are assessed using a questionnaire, survey, or interview procedure, then the data will likely be “impure,” that is, affected by participants' reactions and characteristics. For example, a QUESTIONNAIRE or SURVEY about racial tolerance or sexual matters will likely elicit participants' reactive concerns about the purpose of the research (e.g., who will see the data and what type of responses will seem appropriate). Data are also sensitive to factors such as the gender, race, age, or other characteristics of research personnel. Moreover, some research participants are motivated to “help” researchers, whereas others are less—sometimes, far less—cooperative. Although their hypotheses may sometimes be inaccurate, participants nevertheless usually respond in line with these speculations.

Frequently, researchers themselves have ideas or wishes about how their research will work out. We know that these expectations may affect how the work is carried out (Rosenthal, 1976), as well as subsequent results.

In contrast, unobtrusive methods are those in which participants are unaware of being observed or used as sources of data. The researcher(s) here believe it is important to avoid the usual requirement of obtaining participants' prior consent, that is, their active cooperation. Unobtrusive research often avoids human involvement altogether and makes use of historical or archival material or research strategies such as hidden

tape recorders, microphones, or even hidden observers. Other studies represent research on “say and do”; that is, they compare what participants say they would or would not do in certain situations with what they are actually observed to do. For example, one might telephone landlords advertising rooms or apartments for rent, make simple enquiries as to availability, and then compare the results with those from other conditions in which landlords are led to believe that callers are of a certain race or bear some stigmatizing characteristic, such as being homosexual, a person with AIDS, or a former psychiatric patient needing accommodation. Lee (2000) has also discussed the Internet as a domain for unobtrusive research, such as analysis of “home pages.”

Unobtrusive measures bear ethical pitfalls because their data do not assume the active cooperation or consent of participants. Yet a major goal of social science remains that of gathering, comparing, and contrasting observations from both obtrusive and unobtrusive measures.

UNOBTUSIVE METHODS

For many years, social scientists have stressed the formal aspects of research—we thus have many textbooks on statistics and issues of RESEARCH DESIGN. One problem remains: We know much more about how our research is supposed to transpire than we do about how it actually does. In psychology, much research has assumed, for example, that human beings will simply write down or tell us verbally what they think, feel, or will do or that they will just “respond” automatically to research “stimuli.” Yet we often find a clear contrast between what people say (or what

they say they do) and what they actually do. A related contrast is that between what they do when they know they are being observed and what they do when they assume their behavior is private and unknown to, or unobserved by, others. *Unobtrusive methods* is the name given to research methods that neither depend on nor seek the active involvement or consent of human research participants and frequently are undertaken without participants’ awareness. Some methods, such as CONTENT ANALYSIS, gather data and observations from impersonal sources such as magazines, books, newspapers, Internet material, media presentations, or archival sources.

BACKGROUND

As an illustration of unobtrusive methods used to observe human behavior, the American television series *Candid Camera* became notorious but also respected by social scientists. The series was based on unobtrusively filmed records of people, observed without their knowledge in a variety of real social situations. These individuals proceeded to “be themselves”—usually to their later embarrassment. The staff of *Candid Camera*, for example, removed the engine from a car at the top of a large hill. The car was then “driven” without power down the hill and coasted directly into a service station at the bottom. When the (female) driver said she thought the engine was “running rough,” several (male) station attendants raised the hood of the car; peered in, then appeared stumped by the engine problem they saw, even though there was no engine there to see.

Unobtrusive means *noninterfering*, *silent*, or *in the background*. Thus, a simple though frequently forgotten lesson is taught by unobtrusive methods. That is, whenever appropriate, we should consider research methods that do not themselves adulterate or somehow affect or alter the nature of the data gathered. There are no specific types of quantitative or qualitative data analysis that uniquely define unobtrusive research methods. Moreover, there are neither limitations nor rigid boundaries for defining them. The term *unobtrusive* thus refers only to a general class of methods.

Unobtrusive methods developed historically from the increasing realization, since the 1960s, that many forms of social science research, particularly those involving social interaction between researchers and research participants, are subject to numerous sources

of unreliability and error. The common goal of these methods is to avoid what Webb, Campbell, Schwartz, and Sechrest (1966) referred to originally as REACTIVITY, that is, the tendency of many conventional (obtrusive) methods to give away or communicate to participants what the research is about—what they are looking for, as it were. In turn, participants then “react”; that is, they behave differently than would have been the case had their data been gathered unobtrusively and without their awareness of being a focus of research. One form of reactivity is that the participants perceive or guess correctly what the research objectives or hypotheses are, basing this on cues detected during data gathering. Moreover, we know that many respondents, for example, will respond to QUESTIONNAIRE or SURVEY items to create a “good impression” or respond according to other forms of bias. In some cases, participants’ guesses about a research study may be uncertain or inaccurate, but they will nevertheless affect their responses and behavior. There are multiple sources of data reactivity, including not only participants’ perceptions and hypotheses about the nature and purpose of the research but also effects exerted by characteristics of the researcher and research situation itself.

In recognition of this issue, Webb et al. (1966; see also the revised edition by Webb, Campbell, Schwartz, Sechrest, & Grove, 1981) published their volume *Unobtrusive Measures*. The field of social science owes a great debt to these authors because our knowledge and awareness of these procedures trace largely to their writings. A valuable summary of this area, with many recent examples, has also been provided by Lee (2000). Although the point is often missed, Webb et al. emphasized that they did not totally object to conventional research methods. They indicated, however, that these measures, sometimes of necessity, were often used naively and alone—that is, without being supplemented by or subject to verification from unobtrusive methods examining the same research question or issue. Given this situation, social science often has difficulty in establishing the boundaries of validity and generalizability for its findings. We too seldom know, for example, how well conventional testing or data-gathering procedures will equip us to predict behavior in real-life (as opposed to experimental or laboratory) situations. Conventional methods, as referred to above, are familiar: interviews, psychological tests, qualitative studies, rating scales, surveys, and a host of one-shot studies based on simple, often quite obvious

or transparent questionnaire measures. Thus, in social science, we frequently find, rhetorically put, that the presence and characteristics of our microscope actually serve to cause changes in the behavior of the material or organism under study.

EXAMPLES OF UNOBTUSIVE METHODS

Thus, we describe the unobtrusive or nonreactive method as one that seeks to avoid reactivity and does not require or seek the active cooperation, awareness, or consent of participants involved. Many such studies might therefore be called “say and do” research or, more accurately, say *versus* do. Indeed, Lee (2000) classifies many studies of this type as FIELD EXPERIMENTS. We list a few examples below, for which relevant references and further details may be found in Page (2000). Thus, we might assess the following:

1. The popularity of library or museum materials by unobtrusively measuring and subsequently comparing the extent of disintegration, per unit of time, on the floor surfaces surrounding different types of exhibits (Webb et al., 1966).

2. The extent of customers’ interest in buying certain products, as indicated by extent of pupil dilation (Webb et al., 1966).

3. The extent of racial prejudice in a given locality by observing the extent to which landlords advertising rooms or apartments for rent will communicate false information about room availability to individuals believed to belong (or not belong) to a certain race or to bear some type of stigmatizing characteristic such as being homosexual, a person with AIDS, or a former psychiatric patient now needing accommodation. A variation of this basic method has been used in civil rights and desegregation efforts, that is, in which rooms known to be unrented and available are enquired about by Black persons as potential tenants, sometimes making personal visits to landlords to gather this information.

4. The extent to which clinical therapists or distress center counselors show empathy and related helping skills with their clients by analyzing unobtrusively obtained (without participants’ knowledge) tape recordings of online, telephone-based, or live interactions.

5. The extent to which respondents will indicate high acceptance and tolerance toward Blacks, for example, as determined from an interview,

psychological test, or survey procedure yet be less likely to patronize Black as opposed to White cashiers in cafeterias or to show subtle (e.g., nonverbal or gestural) forms of rejection or hostility when these behaviors are observed unobtrusively over time.

6. The extent to which potential community employers will offer or deny employment to persons alleging to have been former psychiatric patients compared to other individuals making no such reference. Several studies using this basic approach, sometimes including the use of hidden tape recorders, have been performed by Professor Amerigo Farina and colleagues at the University of Connecticut.

7. The extent to which mail, believed to be written to (or from) a psychiatric patient and accidentally "lost" in a variety of locations, will be forwarded (posted) by persons finding such mail.

8. The extent to which differences will be found when students' evaluations of their courses or professors, based on interviews or mandatory written assessments, are compared with the content of unobtrusively obtained recordings of students' waiting-room or cafeteria conversations.

9. The extent to which Black shoppers, unobtrusively observed, might receive poorer service in stores compared to service to Whites or be quoted higher prices for used cars or other merchandise compared to those given to Whites.

10. The extent to which changes in students' morale and school spirit at a university, over time, are reflected in changes in bookstore sales of clothing and supplies bearing their university's colors, logo, or name.

11. The nature of a society's attitudes toward the mentally ill, including changes in these over time, by examining the content of newspaper articles and news items referring in some fashion to the label of "mental illness." One might conduct research of this nature, for example, by examining all Canadian newspaper items and stories archived under this heading in the Canadian Newspaper Index and then comparing their content over both recent and past time periods. The use of archival or "running" records (Lee, 2000) or CONTENT ANALYSIS (i.e., obtaining observations from already existing sources)—quite apart from direct involvement or observation of human participants—is now a popular form of unobtrusive data collection.

A final example concerns the increasing attractiveness of using the Internet to gather unobtrusively obtained data and observations. The Internet

represents a data source that enables the unobtrusive study to explore both the content and methods of self-expression in which online users engage. In addition, the researcher in this domain becomes largely freed of the usual research constraints of time, space, and cost. An excellent discussion of Internet-based research, addressing these points and with many examples, may be found in Lee (2000). For example, the style and content of "home pages" may be studied as a means of learning about individuals, groups, or organizations. Sometimes, information about sensitive research topics may be gathered if one can establish reliable and confidential online contacts. The anonymous nature of much Internet "behavior" also affords an opportunity to study online users in a virtual environment existing quite apart from normal concerns about how one will "look." Patterns of computer usage, communications, and online postings from "chat rooms," online discussions, or newsgroups may also be studied.

ETHICAL CONSIDERATIONS AND CURRENT STATUS OF UNOBTUSIVE METHODS

Moreover, assessing the current status of unobtrusive methods includes considerations about the issue of obtaining INFORMED CONSENT from participants. First we note that many common research methods, prevalent at the time of the first Webb et al. (1966) book, remain still quite popular and prevalent today. Perhaps this reflects the issue of consent; that is, they remain in vogue not necessarily through any inherent or absolute guarantee of validity but because it is usually not difficult to obtain and document participants' consent to take part in them. This perspective is congruent with the current popularity of SOCIAL CONSTRUCTIONISM, that is, the view that research participants must be viewed as genuinely participating in research for which they are providing data. The constructionist view thus sees participants as helping to create the results, as having a "research relationship," a type of coexistence, with the researchers. In this view, facts and knowledge are not discovered (as we generally assume they are) but instead are invented or jointly created by social consensus. (Research participants in psychology, until recently, were called *subjects*, a term that, for social constructionists, implied that they were inert and object-like rather than human beings helping researchers to create knowledge.)

Consequently, then, unobtrusive methods, based generally on data gathering without the cooperation or knowledge of research participants, are hardly in vogue today in terms of methodology or epistemology of research. Of course, for Webb et al. (1966), the active involvement, consent, and cooperation of participants, although appropriate in many contexts, were not intrinsic goals of research. To the contrary, they represented sources of reactivity to be avoided or at least supplemented by other measures. In essence, the dependence on and, in fact, the seeking of data from actively consenting (and collaborating) research participants are effectively a rejection of the very purpose and goals of unobtrusive measures (Page, 2000). Unobtrusive methods are seldom emphasized in current research courses or in the research work of students, despite our concerns about the generalizability and validity of data from reactive methods. Webb et al. reported in the revised (1981) edition of their earlier book, as cited by Lee (2000), that although most social scientists seem generally to have recognized the value of unobtrusive measures, the actual use of the methods is now infrequent.

Unobtrusive measures do involve ethical pitfalls, and in some cases, their use may even be legally precarious. It may be problematic or awkward to record or observe certain behaviors without participants' knowledge or, as some have done, to create simulated emergency situations in public places to observe reactions of the public. Data from unobtrusive methods may sometimes be unreliable or difficult to interpret, no less so than with other methods, so that in some instances, one must consider them with some trepidation. Another question is whether a study should refrain from using unobtrusive measures when another method might be used in which informed consent could be obtained from participants, that is, if the alternative method will not be unduly affected by reactivity. Lee (2000) also describes certain ethical issues arising from unobtrusive studies using the Internet. Many of these concern the difficulty in drawing the line between public and private domains and in safeguarding the confidentiality of online participants where such is critical. We note here that Webb et al. (1966) did not view nonreactive methods as inherently unethical and, in fact, saw them as enabling researchers to sleep better, that is, to gather data without inconveniencing, concerning, or otherwise interfering with the lives of participants.

Increased consideration of unobtrusive methods, consistent with the work of Webb et al. (1966, 1981)

and others, has the potential to augment conventional methods and to move us beyond our dependence on reactive data—thereby effectively reacquainting us with the basic issue of the generalizability of research observations as well as the need to “triangulate,” that is, to use different types of measures in researching a particular problem or hypothesis. We also note Donald Campbell's belief that social science research should ultimately be conducted for others, that is, for the benefit of the community and society. Research using some form of nonreactive methodology, sometimes involving some form of DECEPTION of participants where this can be scientifically justified, has the potential to generate results that are striking, unexpected, and often counterintuitive—and therefore of particular interest and value.

UNSTANDARDIZED

The concept of *unstandardized* can best be understood in contrast to the term *standardized*. Standardization transforms statistics of different metrics to a common metric to permit comparison. In other words, if the statistics are unstandardized (have different terms of measurement), they cannot be compared. Take, for example, the PARTIAL UNSTANDARDIZED REGRESSION COEFFICIENT, or the slope, of a multiple regression equation. Consider a time series of data about Brazil, 1970–1991 (World Bank, 1997):

$$\hat{Y} = -5764 + 110X_1 + 28X_2,$$

where $\hat{Y}$ is the gross national product (GNP) per capita in U.S. dollars, X_1 is the percentage urban population, and X_2 is the net capital inflow in billions of U.S. dollars. Both variables, X_1 and X_2 , turn out to be

significant. The results indicate that a 1% increase in the percentage urban population of Brazil is, on average, associated with an increase in per capita GNP of \$110, and a \$1 billion increase in net capital inflow to Brazil is, on average, associated with an increase in per capita GNP of \$28. However, the unstandardized partial regression coefficients, or slopes, do not indicate which variable, urban population or net capital inflow, has a greater impact on the dependent variable per capita GNP. Although the value of the slope coefficient is greater for the variable percentage urban population, clearly a 1% increase in urban population is qualitatively different from an increase of \$1 billion in net capital inflow. In fact, I can artificially increase the slope coefficient (unstandardized partial regression coefficient) for net capital inflow by changing the terms of measurement to trillions of dollars from billions of dollars. The sizes of the slopes, the unstandardized regression coefficients, do not indicate which independent variable is associated with a greater change in the dependent variable.

To facilitate comparison of the impact of the INDEPENDENT VARIABLES on the DEPENDENT VARIABLE, we can standardize the variables on a common scale to produce STANDARDIZED REGRESSION COEFFICIENTS, also known as beta weights. The values of the independent and dependent variables are standardized by calculating their position in terms of STANDARD DEVIATIONS away from the mean. This procedure produces new values for the variables that are then used to reestimate the regression equation (this procedure can be performed by statistical packages when analyzing the data). The beta weight, or the standardized regression coefficient, is “the average standard deviation change in Y associated with a one standard deviation change in X , when the other independent variables are held constant” (Lewis-Beck, 1980, p. 65). This transformation now permits assessment of which independent variable is associated with a greater change in Y . In the example here, we find that a 1 standard deviation change in urban population is associated with a .99 standard deviation change in GNP per capita, whereas a 1 standard deviation change in net capital inflow is associated with a .17 standard deviation change in GNP per capita. Clearly, urban population seems to be more important for explaining changes in GNP per capita, but net capital inflow is of marginal importance.

The standardization procedure takes advantage of the known properties of the NORMAL DISTRIBUTION to permit comparison of independent variables

in a model. Standardization of partial regression coefficients, however, only permits comparison within a sample. Beta weights cannot be compared across samples to determine, for example, whether the percentage urban population is similarly associated with a large change in per capita GNP in Argentina, assuming the VARIANCES of the independent and dependent variables differ between Brazil and Argentina. A comparison of beta weights across samples can thus artificially alter the value of the beta weights and lead to possibly erroneous conclusions. Instead, it is appropriate to compare a variable, such as the effect of urban population on per capita GNP, across samples with the unstandardized regression coefficient because it is not sensitive to different X variances, and the variables are of the same metric in both samples.

The concept of standardization is employed in other statistical measures and concepts such as the STANDARD NORMAL DISTRIBUTION, STANDARD SCORES, and the CORRELATION COEFFICIENT. The correlation coefficient is a measure of the strength of ASSOCIATION between two variables. This measure is not susceptible to changes in the terms of measurement that afflict the measure of COVARIANCE because the correlation coefficient simply standardizes the covariance by using the standard deviations of each variable to create standard scores. Standardization of the covariance renders a statistic of ASSOCIATION that is more intuitive and thus more useful than the covariance statistic. Because the covariance statistic lacks an upper or lower bound, it does not provide a measure of the strength of the association. We do not know whether the magnitude of the covariance value reflects a strong association or is a product of the terms of measurement of the variables. Standardization ameliorates this problem by forcing the measure of association within the interval of -1 and 1 , with -1 or 1 representing perfect linear association.

The standard normal distribution and standard scores provide the foundation on which much of statistical analysis is executed. The examples of the beta weight and the correlation coefficient illustrated here both use these concepts. Standard scores (also known as Z -scores or standardized variables) are obtained by standardizing the variables using the concept of a standard normal distribution. A standard score of a variable X is expressed as the sample mean subtracted from the values of the variable x_i and then divided by the standard deviation s . The result is a variable with a standard normal distribution—a mean of zero

and a variance of 1. As these examples illustrate, the essence of standardization is to find a common metric on which statistics or variables of different metrics can be evaluated.

UNSTRUCTURED INTERVIEW

The unstructured interview comprises various types: creative, ACTIVE, postmodern, and feminist interviews. They all share a common concern with allowing interviewees as much latitude as possible in answering OPEN-ENDED QUESTIONS and going off in directions of their own. The interview is seen as an interaction accomplished between the interviewer and the interviewee.

The unstructured interview, also called an in-depth interview, does not rely on CLOSED-ENDED or structured questions. The interviewer pursues information about a given topic by asking open-ended questions or merely prompting the interviewee. The interview may be taped or the interviewer may take notes during the interview or, more rarely, shortly after the conclusion of the interview.

For the interview to take place successfully, the interviewer must gain the trust of the respondent. The interviewer may gain trust by relying on his or her academic status and the scope of the study or by temporarily becoming a member of the group under observation; at times, the respondents are paid to participate in the interview (cf. Malinowski, 1989). Unstructured interviews are often practiced in conjunction with PARTICIPANT OBSERVATION; in fact, many of the Chicago school classic studies of the

1930s relied almost entirely on unstructured interviews (Harvey, 1987).

Unstructured interviews have recently taken many forms that differ somewhat from each other. They can be divided into the following subgroups:

Creative Interviewing. In *Creative Interviewing*, Jack Douglas (1985) proposes different techniques for unstructured interviewing, based on his research and that of his graduate students. Traditionally, the interviewer attempts to remain neutral and not to influence the study in any way. Thus, it should not matter who the interviewer is *qua* individual. Douglas feels differently. He argues that there is an unwarranted assumption in unstructured interviewing that the respondent will be truthful in his or her answers. Yet, muses Douglas, people lie all the time in everyday life, so why should respondents be any different? To maximize the chances of truthfulness and full disclosure, Douglas feels that the interviewer needs to offer a *quid pro quo*. The interviewer must disclose a private glimpse in his or her private life to the respondent, thus becoming truly a human being rather than an impersonal neutral interviewer and gaining, it is hoped, the trust of the respondent. In addition, Douglas indicates that information obtained by respondents must be continually checked for veracity by the use of informants. Informants tend to be marginal members of the group studied, and hence they tend to be discontented and likely to divulge information about their group.

ACTIVE INTERVIEW. James Holstein and Jaber Gubrium (1995) moved away from interviews as a one-sided affair in which the interviewer maximizes techniques to gather the best amount of information from the respondent. Instead, Holstein and Gubrium consider the unstructured interview as an active interaction between the interviewer and the respondent. The data gathered are far from neutral. Rather, the interview is the negotiated result reached together by the two (or more) individuals. The results depend on the level of collaboration and ability to interact by the two, who together create a story—the interview. The interview does not take place in a vacuum but is affected by the context in which it occurs. An added relevant dimension for the interview, for Holstein and Gubrium, is determined by *how* the results are achieved (the reflexive analysis of the elements that affect the interview), as well as by *what* is achieved (the substantive findings of the interview).

Postmodern Interview. The postmodern interview is another subgroup of the unstructured interview. POSTMODERNISM is a philosophical set of notions that has permeated many disciplines. Although highly controversial, it has brought some important considerations to the unstructured interview. Postmodernism advocates the demise of meta-theories and PARADIGMS and wishes to revert to studying and understanding the minutiae of everyday life, as viewed by the members of society themselves. Clearly, the unstructured interview can be informed by postmodern notions, especially when addressing the concern with the power structure of the unstructured interview. Traditionally, the interviewer controls the interview—asks the questions, determines what is relevant, decides on the duration of the interview, and chooses how to use the results of the interview. Postmodernists feel that the respondents are being exploited, and to use them and their information for purposes that do not benefit them at all is unethical. Postmodern sociologists reject this model of interviewing in favor of an overtly politically cooperative one. They advocate the study of unprivileged groups, with the open agenda of helping them. This flies in the face of the traditional sociological notion of neutrality and OBJECTIVITY. What results is open partisanship whereby the results of the interview are to be used in a way to aid the group being studied.

Feminist Interview. A final subgroup comes from the feminist interview. Often, the feminist interview is coupled with the longstanding ORAL HISTORY approach. Feminists consider traditional unstructured interviews as highly paternalistic and biased. Both the interviewers and the concerns of the studies tend to be overwhelmingly male centered. For feminists, it is time to be attentive to the concerns of the women interviewed. Also, by introducing female interviewers, the tension in the interview is greatly reduced. Woman-to-woman interviews open the door to more open disclosure of information, as the respondents are freed from the subordinate roles they take in traditional male-female interviews. Thus, they may feel free to address problems and issues they had previously felt unable to disclose. Feminist interviews are intended to help the women studied, not use them and their information.

In concluding, keeping all of the aforementioned variations in mind, the unstructured interview remains a fundamental tool in the quest for sociological

knowledge. The methodology of asking questions and getting answers allows sociologists to understand the meaning of everyday life for its members. The unstructured nature of the interview does not foreclose on the possible answers but leaves a wide-open field, fostering a broader understanding of society.

UTILIZATION-FOCUSED EVALUATION

Utilization-focused evaluation premises that EVALUATIONS should be judged by their utility and actual use; therefore, evaluators should facilitate the evaluation process and design any evaluation with careful consideration of how everything that is done, *from beginning to end*, will affect use. The *focus* is on *intended use by intended users*. The evaluator develops a working relationship with intended users to help them determine what kind of evaluation they need. Utilization-focused evaluation does not advocate any particular evaluation content, model, method, theory, or even use. Rather, it is a process for helping primary intended users to select the most appropriate content, model, methods, theory, and uses for their particular situation. The evaluator collaborates with an identified group of primary users, focusing on their intended uses of evaluation.

V

V. See SYMMETRIC MEASURES

VALIDITY

One of the most important steps in social research is the MEASUREMENT of theoretical CONSTRUCTS. Relating the abstract CONCEPTS described in a THEORY to empirical INDICATORS of those concepts is crucial to being able to empirically examine and test the phenomena under study. The association of an abstract theoretical concept with its empirical manifestation is at the heart of validity.

Validity is generally defined as the extent to which any measuring instrument measures what it is intended to measure. Strictly speaking, however, the only way a researcher can access the validity of a measurement is by validating “an interpretation of data rising from a specified procedure” (Cronbach, 1971, p. 447). The clear implication here is that a measuring instrument can be relatively valid for measuring one phenomenon but invalid for measuring other phenomena. Thus, the measuring instrument itself is not validated, but the measuring instrument in relation to the purpose for which it is being used.

There are three basic types of validity that concern us here: CRITERION-RELATED VALIDITY, content validity, and CONSTRUCT VALIDITY. Each type evaluates validity in a different way, and each has its own uses and limitations.

Criterion-related validity, or predictive validity, is closest to the definition above. A measure is said to be relatively valid if it accurately predicts the results on some other, external measure, or criterion. For example, one validates a written airline pilot’s examination by showing that it accurately predicts how well a group of people can actually fly an airplane. The degree of criterion-related validity is indicated by the correspondence between the test and the criterion. Indeed, this CORRELATION is the only kind of evidence that is relevant to criterion-related validity.

There are two specific types of criterion-related validity. When the criterion exists in the present and is correlated with a current measure, we are dealing with concurrent validity. Predictive validity, on the other hand, focuses on a situation in which the measure predicts a future criterion or outcome. The difference between these two types of criterion-related validity thus concerns the temporal placement of the criterion—now or in the future.

Content validity is another basic type of validity. This type focuses on the extent to which a particular empirical measurement reflects a specific domain of content. For example, a test in world history would not be content valid if it focused only on the history of the United States or Europe. A researcher must take into account several considerations when assessing content validity. First, the researcher must be able to specify the full domain of relevant content. In the example above, a world history test would need to cover all regions of the world as well as the entire period of recorded history. For many abstract theoretical concepts found in the social sciences, it often proves difficult to specify the full domain of content. Second, the researcher must

take a careful sample of this domain for testing. The difficulty here is that it is not always a sample from the full domain of content. Third, the sample of content must be put into a form suitable for testing. Thus, while intuitively appealing, content validation is often difficult to assess in the social sciences.

The third basic type of validity is construct validity. Fundamentally, construct validity focuses on the extent to which a measure performs according to theoretical expectations. Assessing the construct validity of a measure involves three distinct but interrelated steps. First, one must specify the theoretical relationship between two or more theoretical constructs. Second, the empirical relationship between the measures of the constructs must be examined. And finally, the empirical relationship evidence must be interpreted in terms of how it clarifies the construct validity of the particular measure. Thus, if, on the basis of theoretical considerations, it is expected that racial prejudice is more prevalent among less educated people than among those with higher levels of education, one could assess the construct validity of a measure of racism by seeing if it is negatively correlated with education. This example shows that construct validation can be assessed only within a given theoretical context, because it is the context that generates the theoretical predictions that are at the heart of this type of validity. Because construct validation is woven directly into the fabric of social science theory, it is considered more pertinent in the social sciences than either criterion-related validity or content validity.

VARIABLE

A variable is something that varies in value, as opposed to a constant (such as the number 2), which

always has the same value. These are observable features of something that can take on several different values or can be put into several discrete categories. For example, students' scores on an exam are variables because they have different values, and religion can be considered a variable because there are multiple categories. Scientists are sometimes interested in determining the values of constants, such as π , the ratio of the area of a circle to its squared radius. However, statistics involves the study of variables rather than constants.

A quantity X is a random variable if, for every number a , there is a probability p that X is less than or equal to a . A discrete random variable is one that attains only certain values, such as the number of newly elected senators in a given election. By contrast, a continuous random variable is one that can take on any value within a range, such as a person's height (measured in the smallest possible fractions of an inch).

Data analysis often involves HYPOTHESES regarding the relationships between variables, such as "If X increases in value, then Y tends to increase (or decrease) in value." Such hypotheses involve relationships between latent variables, which are abstract concepts. These concepts have to be operationalized into manifest variables that can be measured in actual research.

A basic distinction in statistical analysis is between the DEPENDENT VARIABLE that the researcher is trying to explain and the INDEPENDENT VARIABLES that serve as predictors of the dependent variable. In REGRESSION, for example, the dependent variable is the Y VARIABLE on the left-hand side of the regression equation $Y = a + bX$, whereas X is an independent variable on the right-hand side of the equation.

The starting point in statistical analysis is often looking at the distribution of the variables of interest, one at a time, including calculating appropriate univariate statistics. The changes in that variable over time can then be examined in TIME-SERIES ANALYSIS. Univariate analysis is usually just the jumping-off point for BIVARIATE or MULTIVARIATE ANALYSIS. For example, in ANALYSIS OF VARIANCE, the researcher examines the extent to which experimental conditions affect the variance in the dependent variable.

VARIABLE PARAMETER MODELS

It is usually assumed that the parameter, BETA (β), in a REGRESSION equation relating the INDEPENDENT and DEPENDENT VARIABLES is constant over all observations. But for TIME SERIES, it is possible to model the evolution of the β parameter over time, usually assuming that this evolution follows some common continuous time series process. Thus, the simplest time series variable parameter model is

$$Y_t = \beta_t X_t + \varepsilon_t,$$

where $\beta_t = \rho\beta_{t-1} + v_t$.

Such a model can be estimated by MAXIMUM LIKELIHOOD ESTIMATION methods via the Kalman filter. It is also possible to test for whether the parameters do vary over time (either continuously, as above, or more discretely). These models are also known as stochastic parameter regression models.

VARIANCE. See DISPERSION

VARIANCE COMPONENTS MODELS

Statistical models such as REGRESSION or the ANALYSIS OF VARIANCE partition observed variation into a systematic portion linked to explanatory variables or experimental treatments, and a random portion. Random variation is commonly represented by a single error term. When two or more sources of random variation affect a phenomenon, the random portion of variation can be represented using a variance components model.

Important social science applications of variance components models are in analyses of data from MULTISTAGE SAMPLING designs, generalizability studies assessing the quality of measurements (see GENERALIZABILITY THEORY), experiments including random factors, and longitudinal studies with repeated measures. Variance components models constitute the random part of MULTILEVEL ANALYSIS or HIERARCHICAL LINEAR MODELS.

Consider a simple model for an observation y_{ij} from a two-stage sample: $y_{ij} = \mu_y + a_i + e_{ij}$; μ_y is the population mean, a_i is a first-stage error term, and e_{ij} is a second-stage error term. The first-stage error terms a_i are known as random effects. In an educational study, the first-stage sampling units could be schools, the second-stage sampling units students within schools, and measure y_{ij} the mathematics achievement of the j th student sampled in the i th school. Here, one source of random variation (students) is nested within the other (schools). The corresponding variance components model is $\text{Var}(y_{ij}) = \sigma_a^2 + \sigma_e^2$, where σ_a^2 is the variance component for the first-stage sampling units (schools) and σ_e^2 is the variance component for the second-stage sampling units (students within schools).

The variance components measure the portions of random variation in y_{ij} attributable to different sources. For the example, the quantity

$$\rho = \frac{\sigma_a^2}{\sigma_a^2 + \sigma_e^2}$$

gives the proportion of total random variation assigned to the first-stage units (schools). Known as the INTRAClass CORRELATION, ρ also measures the degree of homogeneity among second-stage units clustered within a first-stage unit.

Using a variance components model takes interdependencies among observations into account when drawing inferences. In the example, one might seek to estimate μ_y from a sample consisting of n_i students from each of M schools, or a total of $N = \sum_{i=1}^M n_i$ observations. The n_i observations on students within a school are not independent, because they share a value of the school-level error a_i . Analyzing the sample as if it contained N independent observations would result in too small a standard error for the estimate of μ_y ; hence, confidence intervals for μ_y would be too narrow and p values associated with hypothesis tests about μ_y too low.

Estimation of variance components usually proceeds under assumptions that random effects are independently and identically distributed with means of 0. Analysis of variance (ANOVA) methods estimate variance components as functions of observed mean squares, making use of the fact that expected mean squares in the analysis of variance can be expressed as linear combinations of variance components. MAXIMUM LIKELIHOOD (ML) and restricted maximum likelihood (REML) methods obtain estimates for variance components by maximizing a likelihood function. This requires assumptions about the distributional forms of random effects, ordinarily specifying normality. ML and REML have become the preferred criteria for estimating variance components. These estimates usually must be obtained via iterative techniques.

As an empirical example, the model above was applied to scores on a 10-item vocabulary test administered to 1,015 respondents nested within 111 primary sampling units (PSUs) in the 1993 General Social Survey. REML parameter estimates are $\hat{\mu}_y = 6.00$, $\hat{\sigma}_a^2 = 0.44$, and $\hat{\sigma}_e^2 = 4.09$. The total variance is 4.53, and the estimated intraclass correlation is 0.10: About 10% of the variance in vocabulary scores lies between PSUs, with the remaining 90% within PSUs. The estimated standard error of $\hat{\mu}_y$ is 0.09, so a 95% confidence interval for the mean is (5.82, 6.18). Ignoring the clustering of respondents within PSUs and analyzing the 1,015 observations as if they were independent, the standard error of the mean is 0.07 and the confidence interval for μ_y correspondingly shorter.

Studies with more than two sources of random variation require more elaborate variance components models. These take different forms depending on the number of random sources and how they are crossed with or nested within one another. In a generalizability study about job performance ratings, for example, several raters might judge performance quality for each of several employees with respect to several job tasks. Raters, tasks, and employees are crossed sources of random variation in the ratings. Assuming no interactions among the three sources, a model for the rating y_{ijk} of the i th employee by the j th rater with respect to the k th task is $y_{ijk} = \mu_y + a_i + b_j + c_k + e_{ijk}$, where μ_y is the mean rating and a_i , b_j , and c_k are the random effects of employees, raters, and tasks, respectively. The variance $\text{Var}(y_{ijk})$ is then modeled as $\sigma_a^2 + \sigma_b^2 +$

$\sigma_c^2 + \sigma_e^2$, where the four variance components refer to employees, raters, tasks, and error, respectively. These variance components are used in calculating generalizability coefficients (analogous to intraclass correlation coefficients) reflecting the dependability of the ratings.

In multilevel regression models, random variation in parameters leads to other variance component models. An example is the simple linear regression of student j 's mathematics achievement (y_{ij}) on IQ (x_{ij}) within the i th of a sample of schools: $y_{ij} = a_i + b_i x_{ij} + e_{ij}$. The school-specific intercepts a_i vary randomly around an average intercept a as follows: $a_i = a + u_i$, whereas the school-specific slopes b_i vary randomly around an average slope b : $b_i = b + v_i$. The random effects u_i and v_i on the parameters of the school-level regressions are sources of random variation in scores y_{ij} , which may be rewritten as $y_{ij} = a + b x_{ij} + u_i + v_i x_{ij} + e_{ij}$. The variance of achievement given IQ is then $\text{Var}(y_{ij}|x_{ij}) = \sigma_u^2 + x_{ij}^2 \sigma_v^2 + 2x_{ij} \sigma_{uv} + \sigma_e^2$, where σ_u^2 is a school-level variance component for intercepts, σ_v^2 is a school-level variance component for slopes, σ_e^2 is a variance component for students within schools, and σ_{uv} is a covariance between the school-level random effects on intercepts and slopes. Quite complex structures of random variation can arise in models with several levels of nesting and multiple random coefficients.

VARIANCE INFLATION FACTORS

Variance inflation factors (VIFs) measure the impact of COLLINEARITY among the predictors in a REGRESSION analysis on the precision of ESTIMATION. The “variances” in question are the SAMPLING variances of the REGRESSION COEFFICIENTS. The term *variance inflation factor* was possibly coined by Donald Marquardt (1970).

Figure 1 The Square Root of the Variance Inflation Factor VIF_j as a Function of the Multiple Correlation R_j From the Regression of x_j on the Other Predictors

Consider the LINEAR REGRESSION model

$$y_i = \alpha + \beta_1 x_{1i} + \beta_2 x_{2i} + \cdots + \beta_k x_{ki} + \varepsilon_i,$$

where y_i is the value of the response variable for the i th of n observations; $x_{1i}, x_{2i}, \dots, x_{ki}$ are the PREDICTOR VARIABLES; ε_i is the error, usually assumed to be distributed independently of the errors for the other observations, with zero mean and constant variance σ^2 ; α is the regression constant; and (in a model in which the predictors are quantitative) the β s are slope coefficients.

The sampling variance of the LEAST-SQUARES estimate b_j of β_j is

$$V(b_j) = \left[\frac{\sigma^2}{(n-1)s_j^2} \right] \left[\frac{1}{1-R_j^2} \right], \quad (1)$$

where $s_j^2 = \sum (x_{ji} - \bar{x})^2 / (n-1)$ is the variance of the j th predictor, and R_j^2 is the squared multiple correlation from the regression of x_j on the other x s. The second factor on the right-hand side of equation (1), $1/(1-R_j^2)$, called the variance inflation factor for b_j , or VIF_j , expresses the degree to which collinearity among the predictors degrades the precision of b_j , relative to similarly dispersed uncorrelated predictors. The square root of the variance inflation factor expresses the impact of collinearity on the size of the confidence interval for β_j .

It is worth mentioning the other, and more common, sources of imprecision in estimation revealed by equation (1): large error variance, σ^2 ; small sample size, n ; and predictors with small dispersion, s_j^2 . As well, it should be pointed out that collinearity must be very strong before the precision of the regression estimates is substantially degraded. Figure 1 plots the square root of the variance inflation factor against the multiple correlation R_j ; even when R_j is as large as 0.8, for example, the square root of the VIF is still less than 2. Multiple correlations among predictors as large as 0.8 are uncommon in social science data.

Variance inflation factors are applicable to one-coefficient terms in linear models, such as quantitative predictors with linear effects. Multiple-coefficient terms—such as a set of dummy regressors representing a categorical predictor—require a more general approach, because correlations among regressors in a related set are affected by inessential changes to the model (such as a change in baseline category for a set of dummy regressors). John Fox and Georges Monette (1992) suggest a generalization of variance inflation factors to cover these situations, comparing the relative sizes of the joint confidence region for a subset of coefficients for correlated and uncorrelated predictors.

The joint confidence region for two regression coefficients is bounded by an ellipse; for three coefficients, it is ellipsoidal, and for more than three coefficients, it is hyper-ellipsoidal. Figure 2(a) shows two “data ellipses”: The solid ellipse is for uncorrelated predictors x_1 and x_2 ; the axes of the ellipse are parallel to the x_1 and x_2 axes. The broken ellipse is for predictors that are highly correlated, $r_{12} = 0.95$; the tilt of the ellipse reflects the positive correlation between the predictors. Both ellipses are scaled so that their “shadows” on the x_1 and x_2 axes are the standard deviations of the predictors; note that both ellipses are centered at the means of the predictors. For bivariate-normal predictors, the data ellipse is also a contour of constant probability density, but regardless of the joint distribution of the x s, the data ellipse is a graphic representation of the dispersion and correlation of the predictors.

The ellipses in Figure 2(b) give 95% confidence regions for the regression parameters β_1 and β_2 assuming identical sample regression coefficients b_1 and b_2 ; these confidence ellipses are rescaled 90-degree rotations of the corresponding data ellipses. Notice that the

Figure 2 (a) Data Ellipses for Uncorrelated (Solid) and Highly Correlated (Broken) Predictors; (b) Corresponding 95% Confidence Ellipses

size of the confidence ellipse for the highly correlated predictors is much larger than the ellipse for the uncorrelated predictors, and that the former ellipse includes values of 0 for both β_1 and β_2 individually (although not simultaneously).

Now consider dividing the regressors in the model into two subsets: one subset $\mathbf{x}_1$, whose coefficients are jointly of interest, and the complementary subset $\mathbf{x}_2$, with the remaining regressors. The generalized variance inflation factor (or GVIF) compares the squared size of the joint confidence region for coefficients associated with $\mathbf{x}_1$ with the squared size of the joint confidence region for similarly dispersed regressors that are uncorrelated with $\mathbf{x}_2$:

$$\text{GVIF}_1 = \frac{\det \mathbf{R}_{11} \det \mathbf{R}_{22}}{\det \mathbf{R}},$$

where $\mathbf{R}_{11}$ is the correlation matrix among the regressors in $\mathbf{x}_1$; $\mathbf{R}_{22}$ is the correlation matrix among the regressors in $\mathbf{x}_2$; $\mathbf{R}$ is the correlation matrix for all of the x s; and $\det$ is the matrix determinant. When there is only one regressor in $\mathbf{x}_1$, the GVIF reduces to the usual VIF.

VARIATION

The term *variation* refers to the dispersion or SPREAD on a VARIABLE. There is no variation if all observations have the same value on the variable. There is variation whenever the observations are not all alike. Variation can be seen as the degree of heterogeneity on the variable.

STATISTICS would be an unnecessary field if variation did not exist. The interesting variable is one that has variation, and statistics seeks to assess the sources of that variation. CENTRAL TENDENCY measures show what value is typical for the variable, but variation measures are needed to show how typical that value is.

For numeric data, variation is defined as the sum of squared deviations from the MEAN (Blalock, 1979, p. 338). If X_i is the i th observation's value on variable X , and if $\bar{X}$ is the mean (see $\bar{X}$), then variation = $\sum (X_i - \bar{X})^2$. The VARIANCE of a variable is defined as its variation divided by the number of observations, N , and the STANDARD DEVIATION is defined as the square root of the variance.

The variation on a variable can be due to either systematic forces (such as other variables that affect the variable of interest) or to ERROR (such as error in measuring the variable). Many statistical techniques, such as REGRESSION and ANALYSIS OF VARIANCE, seek to partition the sources of variation in the DEPENDENT VARIABLE. In regression analysis, the total variation is divided into the variation due to regression and the variation due to error. If all the data points fall along

a straight line in LINEAR REGRESSION, for example, all of the variation is due to regression and none is due to error. The *R-SQUARED* value in regression is the ratio of the variation due to the regression to the total variation of the dependent variable. In analysis of variance, the total variation is partitioned into the portion due to each independent variable separately, possibly the portion due to INTERACTIONS of the independent variables, and unexplained variation. In using these techniques, researchers seek independent variables that minimize the amount of unexplained error variation, constrained by a desire for parsimony in terms of using the smallest possible efficient number of PREDICTOR VARIABLES.

For nonnumeric variables, variation involves examining the dispersion of values. For example, the VARIATION RATIO is one of several measures that can be used to assess the spread of observations on nominal data.

VARIATION (COEFFICIENT OF)

The *coefficient of variation* of a variable is measured as the ratio of the STANDARD DEVIATION of a *continuous* variable to the sample mean of the same variable. Paul D. Allison (1978) suggests that coefficient of variation can be used to compare *relative* variation of two or more groups. This coefficient is usually denoted by *CV* and can be defined as

$$CV = \frac{s_x}{\bar{X}}$$

In addition to conventional measures of sample variation, such as sample variance and standard deviation, researchers can also use the coefficients of variation of multiple groups to compare their *relative variability and homogeneity* with respect to a certain variable, say, *X*. A higher value in *CV* indicates that the group is relatively more heterogeneous. In contrast, a lower value in *CV* implies that the group is more homogeneous.

The rationale for using the coefficient of variation is that a conventional measure of variation, such as VARIANCE (or, equivalently, the standard deviation), is scale-dependent. Basically, if the data are rescaled, the variance and standard deviation are also rescaled. For example, if we double the value of a variable, thus doubling its variance, then the standard deviation also doubles. If we change the scale of annual income from dollars (e.g., 36,000) to thousands of dollars (e.g., 36.0), then the standard deviation will also decrease by a factor of 1000 (such as from 5,500 to 5.5).

The characteristic of scale dependence of standard deviation and variance makes them somewhat misleading for cross-group comparisons. The coefficient of variation provides a possible solution to this problem. Because both the numerator (i.e., the standard deviation of *X*, or s_x) and the denominator (i.e., the mean of *X*, or $\bar{X}$) of the definition of *CV* are scale sensitive, the scaling factor is cancelled out when calculating the coefficient of variation. As a consequence, *CV* is scale insensitive and usually reported as a ratio or a simple decimal number.

To illustrate the advantage of using the *CV* for cross-group comparisons, suppose a researcher is concerned about demographic homogeneity of two communities with respect to annual income. In one community, the mean income is \$26,000 with a standard deviation of \$3,000. In the other community, the average income is \$39,000 with a standard deviation of \$5,000. We find that a larger mean income comes with a larger standard deviation. Therefore, it is useful to assess the size of standard deviation of annual income *relative* to mean income when one attempts to compare these two groups. This leads to two coefficients of variation: $3000/26000 = 0.115$ for the first community and $5000/39000 = 0.128$ for the second community. Note that the difference between these two *CVs* is much smaller than that between the two standard deviations.

Although the coefficient of variation provides a measure for relative dispersion, this coefficient is reported rather infrequently in the social science literature. Jesper B. Sørensen (2002) points out some drawbacks associated with using the coefficient of variation. He argues that combining the mean and standard deviation into one measure sometimes may obscure the true effects of these two factors if both standard deviation and the mean have independent effects on the same response variable. He suggests researchers

use caution when using the coefficient of variation. Allison (1978) also provides more information regarding comparisons between several alternative measures of variation, such as the coefficient of variation and Theil's index.

VARIATION RATIO

The variation ratio is a measure of DISPERSION for NOMINAL VARIABLES. It shows how descriptive the MODE is of the data. It is calculated as the proportion of cases that are *not* in its modal category. The variation ratio ranges from 0 to 1, with larger values indicating greater dispersion on the variable:

$$\text{variation ratio} = 1 - (f_{\text{mode}}/N),$$

where f_{mode} is the frequency of the modal category and N is the total number of cases.

The lower bound of the variation ratio is 0, attained when all cases are in the same category. Thus, zero values show that there is no dispersion on the variable.

The upper bound of the variation ratio is maximal when the mode is 1, meaning that each category has a frequency of 1, so there is complete dispersion on the variable. The variation ratio is then $1 - (1/N)$, which approaches 1 as the number of cases (each unique) is increased. For example, the variation ratio of possible nine-digit Social Security numbers is $1 - (1/1,000,000,000) = .999999999$, because each possible Social Security number is unique.

Say that a variable with k categories has a uniform DISTRIBUTION, with each category occurring with equal frequency N/k . The variation ratio is then equal to $1 - (1/k)$. Thus, its value under a uniform distribution is dependent on the variable's number of categories.

The advantage of the variation ratio as a measure of dispersion is that it is simple to compute. Its disadvantage is that it ignores much of the information in the data because it does not take the full distribution of cases into account. The index of diversity, index of qualitative variation, and information theory-based measures of entropy are measures of dispersion that are affected by the distribution of cases across all the categories (Weisberg, 1992, pp. 69–74).

As an example, consider the distribution of religious affiliation in various countries. About 60% of people in the United States are Protestants, so the variation ratio in the United States on religion would be 0.40. By contrast, the variation ratio would be only 0.10 in Poland because that country is about 90% Roman Catholic. Thus, the variation ratio shows that there is much greater dispersion on religion in the United States than in Poland. However, these values do not reflect the degree of dispersion among the other religions in these countries.

VARIMAX ROTATION. See ROTATIONS

VECTOR

A vector is an entity in a geometric space that has both magnitude and direction. Graphically, the magnitude of the vector is commonly represented by the length of the line segment and the direction by an arrowhead at the end of the segment. Textually, vectors may be represented by their starting and ending points, often with an arrow above indicating direction. For example, $\overrightarrow{AB}$ indicates that the vector starts at point A and ends at point B .

In MATRIX ALGEBRA, a matrix having only one column is called a column vector. Similarly, a matrix having only one row is called a row vector. A common

use of vectors is in REGRESSION analysis (see ORDINARY LEAST SQUARES), where they are used to represent, for example, the set of n observations of the dependent variable in a $1 \times n$ column vector. EIGENVECTORS and their corresponding eigenvalues may also be used in REGRESSION DIAGNOSTICS (see also FACTOR ANALYSIS).

—Timothy M. Hagle

VENN DIAGRAM

In a Venn diagram, overlapping areas of geometric shapes have meanings, facilitating comprehension of related concepts. Ruskey (2001) surveys the history of Venn diagrams and their technical details as a mathematical concept. Kennedy (2002) exposit their use in enhancing understanding of MULTIPLE REGRESSION ANALYSIS, the context in which they are relevant for social science research methods.

A classic Venn diagram is shown in Figure 1, in which the circle marked y represents “variation” in y , the dependent variable, and the circles marked x and w represent “variation” in the explanatory variables x and w , respectively. When y is regressed on x , the blue plus red area represents “information” used by the ORDINARY LEAST SQUARES (OLS) formula to produce its estimate of the slope coefficient of x . If such information represents variation in y uniquely explained by variation in x , the resulting estimate is UNBIASED. More information, reflected by a larger area of overlap, produces an estimate with a smaller variance (regardless of the “truth” of this information!). In the multiple regression context, when y is regressed on both x and w , the OLS estimator uses the information in the blue area to estimate the x slope coefficient, and the information in the green area to estimate the w slope coefficient, throwing away the information in the red area. The information in the red area is not employed because it does not correspond to variation in y uniquely attributable to either x or w . The result is unbiased estimates of the slopes of x and w .

Figure 1 Venn Diagram in Which Colored Areas Represent Information Used by OLS Regression to Create Coefficient Estimates

This interpretation of the Venn diagram in a regression context can be used to exposit several results of interest, two examples of which follow.

1. Increasing the overlap between x and w increases the degree of MULTICOLLINEARITY. This causes the blue and green areas to shrink while the red area grows. Because the OLS formula continues to use the information in the blue and green areas to estimate the slopes of x and w , these estimates remain unbiased, but because there is now less information, their variances increase.

2. Omitting the relevant explanatory variable w will cause the OLS formula to use the blue plus red area to estimate the slope of x . This creates bias, due to inclusion of the red area, but because more information is used, variance decreases. An obvious exception is evident: No bias is created when x and w are orthogonal (i.e., no overlap, so no red area), such as might be the case in a designed EXPERIMENT.

VERBAL PROTOCOL ANALYSIS

Verbal protocol analysis is typically a PILOT STUDY that seeks to do CONTENT ANALYSIS through systematic coding of verbalization of decision-making processes by the research subjects, especially consumers (Kuusela, Spence, & Kanto, 1998).

Verbal protocol analysis focuses directly on the sequence of cognitive events that occurs between the introduction of information stimuli and the decision outcome. Data are collected by setting up experimental manipulation or simply a task, introducing choice simulation, and then instructing subjects to report verbally all personal thoughts involved in the judgment/choice task. These thoughts are typically tape-recorded into protocols, then transcribed, broken into a sequence of task-relevant statements (protocol segments), and content analyzed using a CODING scheme with categories such as paired comparison of alternatives. The thoughts reflecting short-term memory processing and, thus, internal deliberation help to infer on issues such as choice criteria, decision strategies, and regularities. The protocol segments representing different aspects of the elementary information processes can also be analyzed qualitatively and quantitatively.

Verbal protocols, compared with other information-processing methods, provide more information per datum (Arch, Bettman, & Kakkar, 1978). Moreover, by tracing the decision-making process, they also explain it. This is useful in exploratory research, when there is no well-founded theory to guide the investigation of the target process. In addition, a simple coding of the protocol segments may serve as a basis for calculation of descriptive statistics relevant to theoretical issues, such as when and how often noncompensatory decision rules are used.

This methodology has some weaknesses. The need to provide a verbal report may alter what information is attended to in the stimulus (in particular, attention deficiency may arise in case of visual representations) and/or utilize some of the cognitive resources available

to the subject (mixing past and present, resulting in problems of accuracy and validity), thus fundamentally changing the underlying processes used in making a choice or judgment. There are also errors of transmission, commission, and omission. Transmission inaccuracy occurs because of an inadequate vocabulary or insufficient training in effective response capability. Commission error occurs where subjects systematically misreport their cognitive processes to impress the researcher by making their behavior look more rational. Omission occurs when the verbal reports are expected to be comprehensive, but the subject may distort or omit particular elements (prompted cues such as eye fixation patterns may help). The protocol method is also not capable of tracing cognitive processes that never reach consciousness. Such problems can be partially mitigated when protocol analysis is used to determine whether human behavior is governed by self-generated rules (Hayes, White, & Bissett, 1998). To tackle underlying cognitive processes one can also assess three criteria:

- *Relevance.* Participants should be talking about the task at hand, and not about an unrelated issue.
- *Consistency.* Verbalizations, to be pertinent, should be logically consistent with the verbalizations that just preceded them.
- *Memory.* A subset of the information heeded during the task performance should be remembered.

The protocol elicitation methods differ in terms of the following:

- The situation or decision task in relation to which protocol data are collected
- The amount of direction and guidance provided by the interviewer
- The timing of the protocol collection (concurrent vs. retrospective)

Concurrent protocols yielding more protocol segments than retrospective reflect the way information is processed (what, why, how). The focus being on *process*, this method is good for pilot studies. Retrospective protocol data, in the ideal case, are collected immediately after the task is completed, while most of the information is still in the short-term memory

and can be directly retrieved. Research shows that the subject here typically focuses on the *final* choice, and hence, this method is good for studies that focus on the *outcome* of the task.

VERIFICATION

Verification refers to the use of empirical data, observation, test, or experiment to confirm the truth or rational justification of a hypothesis. Scientific beliefs must be evaluated and supported by empirical data. What does this require? Two concepts are fundamental in discussing scientific method: truth and justification (warrant). A hypothesis is true if it corresponds to the way the world is. Justification has to do with the grounds we have for believing a given statement to be true. A hypothesis is rationally warranted if a body of evidence and inference has been provided in support of it. Ideally, the fact that a statement is rationally warranted ought to make it likely that the statement is true. (This treatment makes apparent the relevance of Bayesian theory to scientific inference. The questions have to do with the transmission of rational credibility from one body of beliefs to another.) Philosophers have introduced several concepts and theories on the basis of which to analyze the logical and inferential relations between empirical data and scientific hypotheses, including observation, falsifiability, confirmation, and EXPERIMENTAL method. One of the most important consequences of this extended and complex debate is the conclusion that THEORIES cannot be “verified,” but they can be “confirmed,” “warranted,” or “falsified.”

The general question of scientific inference can be formulated in these terms: Given a body of evidence E and a HYPOTHESIS or theory T, how do we measure the warrant of T given E? Are there logical grounds for answering this question? (This does not define the full task for a theory of scientific method, because scientific method should also give us some guidance concerning the problem of discovering a relevant body of evidence.) It is rare for a scientific hypothesis to be amenable to direct and certain confirmation along these lines: Given E, H is certainly true. That is, it is rare that there is a finite body of observations that suffices to establish the truth of a given scientific hypothesis. This is so for two reasons: First, because scientific hypotheses normally refer to entities, mechanisms, or processes that are not directly observable; and second, because hypotheses and theories normally make universal claims (laws) that go beyond any finite body of observations. Instead, verification normally takes the form of indirect inductive or hypothetico-deductive support for the hypothesis: Given E, H is likely to be true.

Suppose that H deductively implies O, and that the body of evidence E contains “not O.” In this case, E falsifies H. On these assumptions, the body of evidence contains observations that demonstrate that H is false. (For example, suppose the hypothesis H deductively entails that the metal will melt when heated to 500 degrees centigrade. We perform the experiment, the metal does not melt, and we conclude that H is false.) Suppose now that H implies a series of observations $O_1, O_2, \dots, O_n$, and that E contains $\{O_1\}$. (That is, some of the observational consequences of the theory are found to be true.) Does E confirm H, and to what extent? This is the fundamental question of inductive logic and scientific method. What constitutes a significant test and confirmation to the theory? Several logical points are important. No finite list of observations exhaustively confirms a theory with universal generalizations, and different types of additional evidence have very different incremental effects on the credibility of the theory. For example, additional observations of the same type have less epistemic weight than an additional, unexpected observation.

What is an observation? This has been a main source of controversy in the philosophy of science, in that it has long been recognized that there is no sharp and permanent distinction between observation and theory. Virtually all scientific observations are theory-laden. But the essential idea is that an empirical observation

is a scientific belief with a relatively direct relationship between the evidence of the senses and the truth conditions of the statement, based on reliable techniques of data collection to which we can attach high rational credibility. Here, for example, we are to consider direct sensory observation, observation using instrumentation, interviews, records of price data, and so on. Most are not “direct” or “certain.” But they are relatively unburdened by currently controversial theories. This description suggests an approach to empirical confirmation that can be described as the “bootstrapping” method, where the credibility of some beliefs is enhanced by assigning provisional credibility to others; we then return to reassess the provisional beliefs based on the wider set of theoretical beliefs.

Several general approaches to empirical evaluation of scientific hypotheses have been offered in the past century. First is the idea, most deeply explored by Carl Hempel, that we should draw out the deductive consequences of a theory; evaluate the truth of some of those consequences using observation and instrumentation; and assign a degree of warrant to the theory based on the volume of its confirmed observational consequences. This approach constitutes the hypothetico-deductive theory of confirmation, and it represents the logical basis for the experimental method. Second is the idea, advanced by Karl Popper, that the scientific method works primarily through diligent and serious efforts to refute scientific hypotheses. The researcher needs to identify the most unlikely predictive consequences of the hypothesis and make every effort to show that these predictions are not upheld—thereby “falsifying” the theory in question. Only when a theory or hypothesis has withstood serious and varied tests along these lines do we have a rational basis for believing it. The two approaches are logically similar, in that they attempt to assign a degree of empirical warrant to a hypothesis based on the truth or falsity of its deductive consequences. But the underlying assumptions about how confirmation and testing proceed are quite different. Confirmation theory largely assumes that degree of warrant increases through the gradual accumulation of true consequences, whereas falsifiability theory assumes that warrant increases only as a result of our failure to refute the hypothesis in question. Both approaches have generated a large volume of critical discussion. Critical reflection upon classical confirmation theory notes that it is difficult or impossible to provide a purely formal specification of the set of deductive consequences of a theory that serves to

enhance the warrant of the theory. Further discussions of the theory of falsifiability have noted that anomalies are too easy to find in the development of scientific theories, and have attempted to offer a more historically adequate account of scientific belief based on a theory of “scientific research programmes” (Lakatos, 1978).

VERSTEHEN

This German word is usually translated as “to understand” and is often contrasted with “to explain” (*Erklären*). The contrast was used in 19th-century German discussions of the distinctive character of the *GEISTESWISSENSCHAFTEN*—the human sciences—by contrast with natural science. In this context, *verstehen* often refers to understanding from inside, rather than through study of external behavior, and it is often seen as the distinctive method of the human sciences. Equally important, what is produced is a different kind of knowledge from that generated by the natural sciences.

The original source of this idea was probably Vico’s suggestion that we can have deeper understanding of other human beings, including those who lived in the past, than we can ever have of physical phenomena. This is because we share a common human nature. However, this human nature is not a fixed set of

traits but an imaginative capacity, a capacity that both produced and can be used to understand past modes of thought and ways of life. Vico's work was largely neglected in the 18th century but was picked up by the German Romantics.

Dilthey is the most important 19th-century theorist of *verstehen*. He spent most of his long academic career seeking to clarify and develop this notion as the key method of the social and historical sciences. His earliest formulations portrayed it as a psychological process whereby historians project themselves imaginatively into the lives of people in the past, recreating their experience, so as to capture the meanings embodied in texts and artifacts. He believed there was a need for a philosophical psychology, or HERMENEUTICS, that would ground this aspect of historiography, and he set out to provide it. Dilthey's later accounts of *verstehen* portray it as cultural interpretation, rather than as a subjective process. It involves locating what is to be understood in terms of the objective cultural meanings that make up its context. Part of Dilthey's concern here was to recognize historical diversity while resisting epistemological RELATIVISM.

Dilthey's ideas have had considerable influence within the social sciences, notably through Max Weber's *verstehende* sociology (see IDEAL TYPE). However, they have also been subjected to serious challenge. In the 20th century, POSITIVISTS argued that, at best, *verstehen* could generate only hypotheses that still need to be tested, because it does not involve any rigorous form of validation. From the other side, there came criticism from Gadamer, who put forward what he called a philosophical hermeneutics. Where Dilthey saw *verstehen* as a method that is essential to the scientific character of social research, Gadamer treated it instead as a fundamental aspect of human-being-in-the-world. From this point of view, it does not differ from lay forms of understanding, nor does it have the procedural, fixed character of a method. Subsequently, some versions of STRUCTURALISM and POSTSTRUCTURALISM have questioned the very possibility of understanding in either sense.

VIGNETTE TECHNIQUE

Vignettes consist of stimuli presented to research participants. Their purpose is to selectively portray aspects of reality to which participants are asked to respond. They take many forms, including written and spoken narratives, visual imagery, video, and sound.

Like any research method, vignettes address clearly defined research questions, and their form and application will be directed by the research questions posed, the topics under study, and the kinds of participant groups involved. The simplicity of scenarios can help to identify, clarify, and disentangle the complexities of real-world processes. They also provide standardized contexts that can be put toward understanding people's responses to particular situations.

To illustrate one application of the vignette approach, consider Hughes's (1998) QUALITATIVE RESEARCH exploring drug injectors' infection risk behavior. Previous research demonstrates drug injectors' risk behavior to be heavily influenced by situated contexts. Vignettes were used to capture, albeit partially, some of these situations. A short story-book vignette was created, narrating risk behavior scenarios confronting two hypothetical drug injectors. Drug injectors' responses to the vignette were set within an in-depth INTERVIEW GUIDE, demonstrating the utility of vignettes in multimethod research. Hughes (1998) observed that drug injectors related well to the vignette; some enjoyed the story and felt confident to identify possible outcomes for the vignette characters. Furthermore, participants drew from a range of perspectives in responding, including for the vignette characters, their peers, and themselves. These different perspectives helped to minimize the potential SENSITIVE TOPICS of the research and SOCIAL DESIRABILITY BIAS. In application, the vignette exposed some of the constituents of risk behavior contained within the vignette scenarios, including what people considered ought to happen compared with what they believed would be realistic responses in drug injectors' lives.

Vignettes can never completely capture the realities of people's lives, and, like any research method,

their application is contingent on research purposes. Methodological debate on vignettes focuses on the differences between what people might actually do in real-life situations and responses elicited from selective representations of real life featured in the “vignette world.” Critiques of the method, including that of Parkinson and Manstead (1993), argue that vignette data can be understood only within the context of people’s responses to particular scenarios and do not allow GENERALIZATION to understanding real life. Other commentators, such as Loman and Larkin (1976), suggest that some vignette forms, such as video and film, relate better to real life than others, such as written narratives. Notwithstanding, vignettes play a valuable role in augmenting insights into the social world and are well suited to multimethod research. They contribute toward understanding people’s perceptions, beliefs, attitudes, and behavior throughout the social sciences.

VIRTUAL ETHNOGRAPHY

The term *virtual* ETHNOGRAPHY denotes PARTICIPANT OBSERVATION of cultural activities mediated by information and communications technologies, usually the Internet. These online activities are viewed as cultural interchanges in their own right, and the ethnographer is able to participate, observe, and produce holistic descriptions of cultural forms and processes, just as in ethnography in face-to-face settings. The ethnographer might study formation of identities, status hierarchies, power relations, cultural values, and norms of behavior. The ethnography may describe how an online setting, such as the lesbian bar described by Correll (1995), is brought into being by participants as a distinctive cultural space. Virtual ethnography can involve a qualitatively based immersive approach, or it

can extend to more complex mapping and quantification of interaction patterns. The field site might be an asynchronous discussion forum, such as a newsgroup or bulletin board, or a synchronous environment, such as a chat room or multiuser environment (text-based or graphical). In either case, the researcher will keep logs of the messages or interactions together with field notes of his or her observations and reactions.

The ability to observe interactions in many online settings without the permission or knowledge of participants raises an ethical dilemma. Many researchers would argue that consideration should be made of the sensitivity of the topic under discussion and the reasonable expectations of participants on the uses to which their words might be put, before venturing on an observational study. Other problems in the application of virtual ethnography include lack of access to corroborative evidence on informants’ offline lives, and the restriction of analysis to those who actively participate, with the reactions of those who simply read without sending messages (lurkers) remaining invisible (Paccagnella, 1997). This is not an issue when the aim is to describe online culture in its own right, but it is problematic when the aim is to address broader cultural phenomena. An approach drawing on more overt REFLEXIVITY would stress how much ethnographers can learn from their own experiences of interacting with informants through the technology, and it would place more emphasis on understanding experiences of the technological mediation of presence.

Virtual ethnography is closely related to the online community perspective, which holds that the social formations found in, for example, Internet newsgroups can be seen as communities in their own right (Baym, 2000). The social formations in online space are held to be deeply meaningful to participants, despite the lack of face-to-face interaction and potential absence of a long-term commitment. Hine (2000) argues that the online community perspective encourages conservative interpretations of the ethnographic approach. An alternative conception of virtual ethnography offers the potential for spatially innovative methodological approaches, adapting ethnographic sensibilities to explore cultural connections across a variety of online and offline settings. Virtual ethnography thus becomes a more broadly applicable methodological approach, encompassing a wider range of topics than the cultures of the Internet alone.

VISUAL RESEARCH

Visual research covers a range of methods and practices that involve the use of visual media and technologies at all stages of research. Since the early 1990s, the use of the visual in social science research has increased dramatically for two reasons. First, theoretical shifts within the social sciences have led researchers to recognize that visual materials are not necessarily more subjective than verbal or written data. Second, new visual media and technologies of increasingly high quality, lower cost, and greater ease of use are available. Consequently, a growing number of researchers use video, photography, drawing, and multimedia in their work.

Although the term *visual research* has become commonplace, visual research is rarely purely visual, but involves the combination of visual and verbal or written methods of doing research and representing this work to others. Therefore, visual methods should not be used in isolation from established methods, but are a means of recognizing and accounting for the importance of visual experience, knowledge, and communication in everyday life and human perception. Visual research may consist of the following:

1. Analysis of the content, process of production, or uses of existing visual images, involving qualitative or quantitative CONTENT ANALYSIS (Rose, 2001).
2. Production of visual images as part of a research project to visually document activities and events, or in collaboration with informants to produce images that represent particular ideas, understandings, or worldviews (Banks, 2001; Pink, 2001).
3. Use of images in interviewing to elicit responses from informants (see Banks, 2001; Pink, 2001).
4. Visual observation of events and activities (Emmison & Smith, 2000).

Often, individual researchers mix different visual methods in the same project with other methods, such as analysis of written texts, IN-DEPTH INTERVIEWING, or PARTICIPANT OBSERVATION.

Visual research is represented in a number of ways, depending on the medium used and the research objectives. It includes using photographs in written publications; photographic exhibitions or essays; ethnographic FILM AND VIDEO; and interactive hypermedia projects using multiple media and published online, on CD-ROM, or on DVD.

THE HISTORY OF VISUAL RESEARCH

Visual methods were first used in sociology and anthropology in the early 20th century. This mainly involved what has been called early “ethnographic photography” of poverty in Europe, colonial subjects overseas, and the production of films about other cultures made during anthropological and exploratory expeditions. Much of the scientific image production of this period has recently been heavily critiqued as exoticising and part of the oppressive colonial project. However, these images are valuable research documents. Later in the 20th century, two landmark projects signify further development in visual research. *Nanook of the North* (1921) has been heralded as the first ethnographic film. Representing the everyday challenges and joys of the lives of North American Eskimos, *Nanook* set the scene for many of the debates that have followed in ethnographic filmmaking throughout the 20th century. In 1942, Mead and Bateson’s photographic study *Balinese Character* was published. An attempt to document Balinese behavior visually, this work fitted with the aims of social scientists of its times—to produce objective visual data about human activity. The question of whether visual images could be objective became a key issue in 20th-century debates.

In the 1980s and 1990s, a changing theoretical atmosphere lent momentum to developments in visual research. The idea that OBJECTIVITY could ever be truly achieved was challenged across the social sciences, particularly among qualitative researchers. Instead, the

notion of REFLEXIVITY—researchers' self-awareness of their subjectivity and how this affects the type of data produced—became increasingly important in QUALITATIVE RESEARCH. In this climate, it became clear that visual data were no more likely to be too subjective to produce reliable materials than any other data, and researchers could make convincing arguments for using the visual in their research and representation of their work.

CONTEMPORARY USES OF VISUAL RESEARCH

Contemporary visual researchers largely use photography, video, drawing, and hypermedia in their work. There are often no hard-and-fast rules regarding which visual methods or media are most suitable. Methods often have to be designed specifically to fit with wider projects and to suit the particular groups of people with which the researcher is working. For example, Banks describes how he photographed as part of participant observation during a festival in India. His informants showed him what was important to them at this event by asking him to photograph key individuals and activities. Through this, he confirmed that his own understanding of the importance of these people and actions was correct (Banks, 2001, pp. 45–47). I experienced similar “informant-directed photography” when researching the Spanish bullfight—my informants asked me to take photographs, through which I learned about my own and their understandings of the bullfight (Pink, 2001). The photographs produced under such circumstances may also be used in photo-elicitation interviews, which allow researchers and informants to discuss the meanings and content of visual materials. In-depth interviews may also be the context in which images are produced. For example, in research about people's relationships with their homes, I videotaped interviews that consisted of tours of each informant's home, led by the informant and guided by my checklist of questions. This allowed me to collaboratively explore with my informants the visual aspects of their home and the meanings that different objects, images, and areas of the home held for them. In these examples, visual methods are not used as distinct from established methods; rather, they are integrated as aspects of participant observation or in-depth interviewing.

However, this integration is not entirely straightforward. Using visual methods raises new ethical

issues. Unlike research represented only in written form, the anonymity of informants who appear in visual materials cannot be guaranteed. Therefore, such work requires that agreements are carefully made and thought out with informants and other stakeholders in the research before work begins.

Visual research methods are becoming increasingly popular among researchers. They are necessarily employed and understood slightly differently across the social sciences because in each instance, they are informed by the theoretical and methodological priorities of the discipline concerned.

VOLUNTEER SUBJECTS

Volunteer subjects (individuals who volunteer to participate in a research investigation) became a focus of attention in the 1960s and early 1970s, stemming from findings that volunteers may respond differently from how nonvolunteers in the general population would respond. Ralph L. Rosnow and Robert Rosenthal (1970) suggested that SYSTEMATIC ERRORS resulting from volunteer bias, although not easily discerned, may exert a subtle influence on experimental and nonexperimental social science research. Through experimental studies, as well as an integrative review of extant literature, Rosenthal and Rosnow (1975) showed that volunteers differed from nonvolunteers in at least 17 characteristics (including education, social class, intelligence, sociability, and approval motivation), and that volunteer subjects are overly sensitive and accommodating to DEMAND CHARACTERISTICS.

According to Rosnow and Rosenthal (1997, pp. 89–91), these findings have at least three practical implications for the social scientist. First, using only volunteer subjects may serve to weaken the explanatory power of the scientific model under study, because the

volunteer effect is usually not addressed explicitly as a variable in the model. A second implication has to do with the GENERALIZATION of research results to a population that typically includes nonvolunteers. A third implication pertains to ethical considerations as set out in the Belmont Report, developed in 1974 by a national commission in the United States charged with the task of formulating guidelines that would protect the rights and welfare of human research participants in biomedical and behavioral research (National Commission, 1979). These guidelines specified that only volunteer subjects could be used in most research investigations. In effect, this development implied that the volunteer problem could not be eliminated in RESEARCH DESIGN, only controlled or corrected for. Even so, precise estimation of the extent of BIAS remains a daunting task, because population parameters are rarely known. The best that the scientist can do in most instances is to speculate on the direction of the bias and interpret results accordingly. Fortunately, our knowledge of reliable characteristics of volunteers, and the reliability of volunteering for various types of studies, listed by Rosnow and Rosenthal (1997, pp. 95–98), can be used in this speculation.

An issue related to the volunteer subject is that of the pseudovolunteer, a verbal volunteer who fails to show up for a research appointment. Early studies had shown that research conclusions, including those examining

differences between volunteers and nonvolunteers, depend significantly on whether pseudovolunteers are included with the volunteer or the nonvolunteer group. Through a meta-analysis of research reports, Rosenthal and Rosnow (1975) found that, on average, approximately a third of those volunteering did not keep their appointments; more recent studies have confirmed that the MEDIAN pseudovolunteering rate has not changed noticeably since 1975.

W

WALD-WOLFOWITZ TEST

The Wald-Wolfowitz (1940) test is a quick and easy test of the NULL HYPOTHESIS that two mutually independent random samples have been drawn from POPULATIONS that are identical. The test is completely general and is not very powerful against any specific kind of difference between the populations.

In order to carry out the test, the two sets of sample data, say m X s and n Y s, are pooled together and ordered from smallest to largest in a single array of $m + n = N$ observations, keeping track of which sample produced each observation. Then, the observations in the pooled array are replaced by X s and Y s that represent the respective populations of origin. If the X s and Y s are well mixed in this pooled array, there is no reason to think that the populations are different in any way. If the X s and Y s exhibit a pattern, this would suggest that there is a difference. For example, if most or all of the X s precede most of the Y s, this is evidence suggesting that the Y population tends to have values of larger magnitude than the X population.

In this pooled arrangement of m X s and n Y s, a run of X s is defined as a sequence of X s that is preceded and followed by one or more Y s or no letter at all. A run of Y s is defined similarly. The Wald-Wolfowitz test statistic T is the total number of runs of either X s or Y s. A large number of runs results when the X s and Y s are well mixed, and therefore, a large value of T tends to support the null hypothesis of identical populations. A small number of runs suggests that there is a pattern, and hence, the populations are not the same. Therefore, the null hypothesis should be rejected for small values

of T . Tables of the exact null distribution of T and/or CRITICAL VALUES of T are available in some books on nonparametric statistics. For larger sample sizes (m and n at least 10), an approximate test can be based on a standard NORMAL DISTRIBUTION with the following test statistic that is a function of T and incorporates a continuity correction to improve the accuracy:

$$Z = \frac{T + 0.5 - 1 - (2mn/N)}{\sqrt{\frac{2mn(2mn-N)}{N^2(N-1)}}}.$$

As an example, suppose that a random sample of six government economists (G) and seven academic economists (A) were asked to predict the overall percentage change in the CPI over the previous year. The data are as follows:

G: 3.1, 4.8, 2.3, 5.6, 0.1, 2.9

A: 4.4, 5.8, 3.9, 8.7, 6.3, 10.5, 10.8

Do the two sets of predictions come from the same population?

We pool the data into a single array as follows, with the government data values italicized.

0.1, 2.3, 2.9, *3.1*, 3.9, 4.4,
4.8, 5.6, 5.8, 6.3, 8.7, 10.5, 10.8

In terms of G and A, this arrangement is GGGGAAGGAAAAA, with a total of four runs, giving $T = 4$. The left-tail p VALUE from the table in Gibbons (1997, p. 483) for $m = 6$, $n = 7$ is 0.043. Using the large sample approximation, we obtain $Z = -1.73$. The left-tail p value from a table

of the standard normal distribution is 0.0418. This provides a very close approximation to the exact value. We reject the null hypothesis at the .05 level and conclude that the distributions are not the same.

Note that actual measurements are not necessary to carry out the test, as long as the pooled array can be formed. This Wald-Wolfowitz two-sample test is included in the STATXACT computer software package.

WEIGHTED LEAST SQUARES

Weighted least squares (WLS) is an extension of ORDINARY LEAST SQUARES (OLS) regression that weights each observation according to some criterion, such as differences in the accuracy of estimates or error variances. In regular OLS, SLOPE estimates are found by minimizing the sum of squares, $\sum E_i^2$, where E represents the residuals from the regression. That is, we minimize the differences in the square of the actual values from the predicted values from the regression equation. WLS extends this model by minimizing the sum of the weighted least squares $\sum w_i^2 E_i^2$, where w represents a weight applied to each observation. Estimates from a WLS regression are interpreted in exactly the same manner as estimates from OLS. WLS is also efficient and shares with OLS the standard procedures for statistical inference (e.g., CONFIDENCE INTERVALS and hypothesis tests).

WLS is most frequently used in the social sciences when HETEROSKEDASTICITY (nonconstant error variance) is present in a regression analysis. The two problems associated with heteroskedasticity—inefficient estimates and biased standard errors—can be limited using weighted least squares. WLS can be used when the functional form of the relationship is linear or nonlinear.

Before WLS can be implemented to correct for heteroskedasticity, however, it must be known that the error variance is systematically related to one of the independent variables. Because this is not known before fitting a regression model, weights are typically found by examining the residuals from a preliminary OLS model. A common pattern of heteroskedasticity is the increase in error variance as the value of an independent variable, X , increases. In such cases, the variance of the errors is proportional to X , and thus, $1/X$ is usually an effective weight for computing the weighted least squares estimates. A plot of the log of the Studentized residuals against the fitted values can help detect this phenomenon.

The disadvantage of using WLS to correct for heteroskedasticity is that we require knowledge of the relationship between the errors and a particular independent variable. Because this cannot always be determined, OLS with robust standard errors is often used as an alternative. Unlike WLS, the use of robust standard errors does not change the OLS regression coefficients, but rather only increases the size of the standard errors. In other words, the use of OLS and robust standard errors will improve statistical testing, but it will not necessarily provide reliable coefficient estimates. As a result, if the pattern of heteroskedasticity can be determined, WLS is a better choice than OLS with robust standard errors.

When a nonrandom pattern in error variance occurs in a TIME SERIES, a related method, GENERALIZED LEAST SQUARES, is used in place of weighted least squares. Iterated weighted least squares (also called iteratively reweighted least squares) can also be used to fit GENERALIZED LINEAR MODELS. Finally, weighted least squares is also used in LOCAL REGRESSION to find local estimates and in ROBUST regression to lessen the impact of influential cases on the regression estimates.

WEIGHTING

Weighting is a method used to estimate a characteristic of a population when data are collected from only a sample. Weighting a sample typically consists of attaching a multiplicative factor called a weight or case weight to each sample observation. An estimate of the population characteristic is the sum of the sample observations where each observation is counted proportional to its weight. In this sense, weighting is a convenient method for implementing a statistical estimation procedure to make inferences from a sample to the full population. Common synonyms for the weight are the *raising*, *inflation*, or *expansion factor*. These terms are descriptive because the weight inflates the sample to the population.

WEIGHTING FOR PROBABILITY SAMPLES

Some method of weighting is used to analyze the observations for almost all samples. Even unweighted analysis of a sample is a weighting scheme with all the case weights equal to unity. Weighting procedures differ depending on the application. With PROBABILITY SAMPLING, weighting the observations produces unbiased, or nearly unbiased, estimates of the population characteristic, where UNBIASED means the average of the estimates computed for all possible samples equals the population characteristic. For example, to compute an unbiased estimate of the population total from a simple random sample of size n from a population of size N , the weight for each observation is N/n . More generally, the reciprocal of the probability of selecting the unit in a probability sample is often called the base weight.

The base weight may be adjusted to compensate for units that do not respond or units that were not covered in sampling. For example, in TELEPHONE SURVEYS, the base weights may be adjusted to account for nonresponding households and for households without phones. Another reason for adjusting the base weights is to implement a more sophisticated estimation technique, such as ratio and regression estimators that take advantage of auxiliary data to improve the precision of the estimates.

WEIGHTING FOR OBSERVATIONAL SAMPLES

The main goal of weighting in observational samples selected without using probability sampling is also to reduce bias, but in this case, SELECTION BIAS is

the primary concern. For example, in an observational study of voters, the weights or balancing factors might be developed so the weighted sample matches the age, sex, and race of the population of registered voters. The objective of the weighting is to reduce the bias in the estimates that might result from having a sample that does not match the distribution of the population.

Standardization is an analytic tool frequently used to analyze epidemiological studies. Standardization is also used to make it easier to compare samples that have different compositions of members of the population. Kish (1987, pp. 113–115) discusses standardization as a method of weighting in observational studies to reduce selection biases. He shows that standardization is a weighting technique that eliminates the effect of unequal subgroup sample sizes and the bias associated with these unequal sample sizes. For example, suppose an equal number of male and female patients are treated for a disease, but the sample taken to evaluate the treatment contains more females than males. Weights may be attached to the sampled patients so that the weighted number of males equals the weighted number of females.

HISTORICAL DEVELOPMENT

Before high-speed computers were available, weighting using case weights was time-consuming and error-prone. As a result, self-weighting samples—in which every sampled unit has the same probability of selection and the same case weight—were very popular. With the introduction of computers, machine-readable cards containing the data from the observation were reproduced to properly represent units selected with unequal selection probabilities. For example, if some observations were sampled with a probability of $1/10$ and others were sampled with a probability of $1/20$, then the cards corresponding to those sampled at $1/20$ were duplicated.

The base weight for sampled unit i , w_i , is the reciprocal of the probability of selection and is a number between 1 and N . Consequently, it is natural to think of sampled unit i as representing w_i units in the population. Although this may be useful for understanding the idea of sampling and weighting, it loses its appeal when more advanced methods of weighting are considered. For example, a regression estimator is the base weight multiplied by an adjustment factor, and the adjusted weight may be less than zero for some cases. A negative regression weight does not mean that the sampled observation represents a negative number of

units in the population. In this situation, it may be better to consider the weight simply as a tool for calculating an estimate of the population.

EXAMPLE

Suppose a STRATIFIED simple random sample of schools is to be selected. The list of all schools in the population is divided into five strata based on the number of enrolled children. Every school in stratum h ($h = 1, 2, \dots, 5$) has a probability of selection equal to n_h/N_h , where N_h is the total number of schools in stratum h and n_h is the number of sampled schools in stratum h . The base weight for school i in stratum h is $w_{hi} = N_h/n_h$, the reciprocal of the selection probability. If only r_h sampled schools respond, a simple adjustment of the base weight is n_h/r_h , the reciprocal of the stratum response rate. The product of the base weight and the nonresponse adjustment is the nonresponse adjusted weight $w'_{hi} = N_h/r_h$ for responding school i in stratum h .

If the total number of public and private schools in the population is known from a census of the schools (say X_1 is the number of public schools and X_2 is the number of private schools), then a poststratified or ratio estimator can be computed. Weighting for the poststratified estimator is very similar to weighting for standardization. The adjustment factor for all responding public schools is $X_1/\hat{X}_1$, where $\hat{X}_1 = \sum w'_{hi}\delta_{hi}$ and $\delta_{hi} = 1$ if school i in stratum h is public, and it is zero otherwise. The factor for private schools is $X_2/\hat{X}_2$, where $\hat{X}_2 = \sum w'_{hi}(1 - \delta_{hi})$. The weights for the poststratified estimator are then $w''_{hi} = w'_{hi}X_k/\hat{X}_k$, where $k = 1$ for public schools and $k = 2$ for private schools. Because both the nonresponse adjusted weights and the poststratified weights could be used to produce estimates of the population, this example points out that the weighting scheme is not unique.

WELCH TEST

The t -TEST of equality of means in two independent samples is relatively robust to violations of assumptions of variance homogeneity (HOMOSKEDASTICITY) and distribution normality within each sample (Wilcoxon, quoted in Algina, Oshina, & Lin, 1994; Winer, 1962). However, the t -test can result in wrong decisions if sample sizes and variances of the two populations are unequal. If the smaller sample has a larger variance, the ordinary t -test favors H_1 ; if the larger sample has a larger variance, H_0 is favored. The Welch test (Welch, 1947) corrects these deviations of ordinary t -test. If sample sizes are equal, the test statistic of the ordinary t -test and the modified t -test of Welch have the same values, but DEGREES OF FREEDOM differentiate. Welch's approximation generally results in lower degrees of freedom.

The test statistic of the Welch test is denoted by

$$t_{\text{Welch}} = \frac{(\bar{x}_1 - \bar{x}_2)}{\sqrt{(s_1^2/n_1) + (s_2^2/n_2)}}.$$

Degrees of freedom are calculated by

$$df_{\text{Welch}} = \frac{1}{[c_1^2/(n_1 - 1)] + [c_2^2/(n_2 - 1)]},$$

where $c_i^2 = (s_i^2/n_i)/[(s_1^2/n_1) + (s_2^2/n_2)]$ for $i = 1$ or 2.

The Welch test should be used if variances are unequal (heteroskedasticity). The assumption of homoskedasticity can be tested by running Levene's F TEST, for example.

Illustration: Two groups are compared (see Table 1). Group 1 consists of 10 cases and has a mean of 10.0 in the analyzed variable X_1 . Group 2 consists of 40 cases. The mean of variable X_1 has a value of 12.0.

The variances in the two groups differ significantly (see Table 2). The value of Levene's F test is 8.5983

Table 1 Group Statistics

	Group	N	Mean	Std. Deviation
X_1	1.00	10	10.0263	0.9438
	2.00	40	11.9805	2.9635

NOTE: These are the results of a simulations study in which 100 simulations were run. For the first group, a normal distribution with mean 10 and variance 1 was assumed, and for the second group, a normal distribution with mean 12 and variance 3.

Table 2 Independent Samples Test

		<i>Levene's Test for Equality of Variances</i>		<i>t-Test for Equality of Means</i>		
		<i>F</i>	<i>Sig.</i>	<i>t</i>	<i>df</i>	<i>Sig. (2-tailed)</i>
X1	Equal variances assumed	8.5983	.0124	−2.0697	48	0.933
	Equal variances not assumed			−3.5417	42.9571	0.231

NOTE: These are the results of a simulations study. The specification of the study is described in Table 1. The values reported are averages. The F -value is the average over 100 simulations, the significance level of the F -value is the average over 100 simulations (and not of the value 8.5983), and so on.

(average of 100 simulations). The computed error level of 0.0124 (average of 100 simulations) is lower than the chosen threshold value of $p < .05$ for the significance level. Thus, the Welch test should be used, the results of which are noted in the second row of Table 2. The test statistic is equal to -3.5417 , and the degrees of freedom are 42.9571. The test statistic is significant if a threshold value of $p < .05$ is chosen for the significance level. In contrast, the ordinary t -test presents no significant results. The reason for this difference is that the ordinary t -test favors H_0 if the larger sample has a larger variance. The example is based on a simulation, and hence, the exact test statistic is known. It has a value of -3.51 and is significant for the selected threshold value of $p < .05$. However, the differences between the two tests dissipate if sample sizes are increased, the variance of Group 2 is reduced, or the number of cases is allocated more equally to the two groups. If, for example, Group 1 consists of 20 cases and Group 2 of 80, both tests result in significant differences [ordinary t -test: $t = -2.9842$ ($p < 5\%$); Welch test: $t_{\text{Welch}} = -5.0580$ ($p < 0.1\%$)].

The Welch test is commonly implemented in statistical software packages such as SPSS or SAS. The test becomes very conservative, favoring H_0 , if the underlying distributions get longer and the sample sizes decrease (e.g., from 20 to 10 in each group) (Yuen, 1974). Like the ordinary t -test, the Welch test can result in biases in both directions (favoring H_0 or H_1) if the underlying distributions are (very) skewed (Algina et al., 1994), especially if SKEWNESS in different directions causes problems. Depending on the amount and kind of skewness, combined or total sample sizes of 40, 80, or, in very extreme situations, 200 cases are needed in order to get sufficient results (Algina et al., 1994).

Good textbooks often recommend to test whether observed distributions in each group deviate from

normal distribution (see KOLMOGOROV-SMIRNOV TEST) if sample sizes are small, and to use a nonparametric test (e.g., MANN-WHITNEY U or WILCOXON rank sum test) if the assumption of normality is violated. A wrong interpretation of such advice, sometimes found in textbooks and research methods, is that the total distribution should be normal. Furthermore, deviations from normality do not necessarily equate with poor performance of the t -test or Welch test. Yuen (1974), for example, notes excellent Welch test results in the case of underlying uniform distributions for small sample sizes (e.g., for $n = 10$ for each group).

Skewness, rather than deviations from normality, seems to be an important factor. Therefore, it is recommended that one should test for skewness if combined sample sizes are smaller than 200, run a t -test or Welch test and a nonparametric test, and compare the results of both tests if data are skewed unless more experiences are available. In smaller samples, outliers may cause heteroskedasticity and skewness. Hence, the data should be checked for outliers.

WHITE NOISE

In general, white noise is an unsystematic variable representing unmeasured properties. The phrase is most often used in the study of TIME SERIES variables, which exhibit AUTOCORRELATION (i.e., current values are correlated with earlier values). The most common is a first-order process, where values at time t are correlated with values at time $t - 1$. An example might be the annual U.S. unemployment rate, 1955–2002. It is easy to imagine that the unemployment rate in the current year is closely predicted by the unemployment rate from the previous year. Of course, some time series may show, or be transformed to show, no autocorrelation at all, at any LAG. Then, lagged values do not predict subsequent values, and the variable appears driven by a STOCHASTIC, or random, process referred to as white noise. If the variable under study is actually a RESIDUAL from a REGRESSION equation, it might be useful to test its status as a white noise process. Bartlett has proposed a white noise test. Supposing the regression residual was found to be white noise, then the need for the usual autocorrelation corrections to achieve more efficient estimates would disappear.

—Michael S. Lewis-Beck

WILCOXON TEST

The Wilcoxon (1945) test, also known as the Wilcoxon signed-rank test, is the nonparametric counterpart of the Student's T -TEST for the mean in the case of one sample, and the paired-sample Student's t -test for the mean difference in the case of paired samples. We discuss it here in the context of paired samples, because that is its most frequent use.

Let $(X_1, Y_1), (X_2, Y_2), \dots, (X_n, Y_n)$ be a RANDOM SAMPLE of n pairs drawn from a bivariate distribution. We want to make an inference about the mean difference between the X s and Y s in the POPULATION. The first step is to take the differences between the X and Y observations in each pair, $D_i = X_i - Y_i$. Because the difference between the X population mean and the Y population mean is the same as the mean μ_D of the $D = X - Y$ difference population, the NULL HYPOTHESIS is $H_0: \mu_D = 0$.

To carry out the Wilcoxon test, the absolute values of the differences $D_1, D_2, \dots, D_n$ are arranged from smallest to largest, keeping track of the original sign of each difference. Then, these absolute values are assigned integer ranks from 1 to n . The test statistic T is the sum of the ranks of those differences that were originally positive. A large value of T suggests that the mean of the X population is larger than the mean of the Y population and, hence, calls for rejection of H_0 in favor of the positive alternative $H_1: \mu_D > 0$. Alternatively, a P VALUE can be calculated as the right-tail probability of a value as large as or larger than the observed value of T . Tables of the exact null distribution of T and/or CRITICAL VALUES of T are available for small sample sizes in Gibbons (1993, 1997). For larger sample sizes, an approximate test can be based on a standard NORMAL DISTRIBUTION with the following test statistic that is a function of T and incorporates a continuity correction to improve the accuracy:

$$Z = \frac{T - 0.5 - [n(n+1)/4]}{\sqrt{n(n+1)(2n+1)/24}}.$$

Any differences that are equal to zero are ignored and n is reduced accordingly. If any of the absolute values of the differences are tied, each of those tied at any given value is assigned the same midrank, defined as the average of the ranks those differences would have been assigned if they were not tied.

As an example, suppose that a random sample of 10 people who drive automobiles was selected to see whether alcohol has an adverse effect on reaction time. Each driver's reaction time was measured both before and after drinking a beverage containing 2 ounces of 80-proof alcohol. The data, measured in seconds, are shown in Table 1. If the alcohol has an adverse effect on reaction times, the sample differences, After – Before, will tend to be large and positive. These differences, their absolute values, and ranks are also shown in Table 1.

The value of the test statistic is $T = 48.5$ with $n = 10$. The exact right-tail p value from Gibbons (1993, p. 68) is 0.0165. The large sample approximation gives $Z = 2.08$ with a left-tail p value of 0.0188. In both cases, the conclusion is to reject the null hypothesis and conclude that alcohol does have an adverse effect on reaction time.

The Wilcoxon test is valid under the assumption that the population distribution of differences is symmetric and continuous. The normal approximation is reasonably accurate for sample sizes of at least 10, and it is

Table 1 Calculation of Wilcoxon Test Statistic

Subject	Before	After	Difference	Absolute Value	Rank	Positive Rank	Negative Rank
1	0.68	0.73	0.05	0.05	5.5	5.5	
2	0.64	0.63	−0.01	0.01	1.0		−1.0
3	0.68	0.66	−0.02	0.02	2.0		−2.0
4	0.82	0.92	0.10	0.10	9.5	9.5	
5	0.58	0.68	0.10	0.10	9.5	9.5	
6	0.80	0.87	0.07	0.07	8.0	8.0	
7	0.72	0.77	0.05	0.05	5.5	5.5	
8	0.66	0.70	0.04	0.04	3.5	3.5	
9	0.88	0.84	−0.04	0.04	3.5		−3.5
10	0.73	0.79	0.06	0.06	7.0	7.0	
						48.5	

improved by incorporating a correction for ties in the Z statistic. The test is almost as powerful as Student's *t*-test for normal distributions and can be more powerful for other distributions. Many computer packages of statistical tests include this test.

A different test that is frequently called the Wilcoxon test is the Wilcoxon rank sum test for the null hypothesis of equal means in two mutually independent random samples and is equivalent to the so-called MANN-WHITNEY U-TEST.

WITHIN-SAMPLES SUM OF SQUARES

An ANALYSIS OF VARIANCE is used to determine whether there are differences in the means of a variable for different groups. This question can also be stated as whether there is an effect of a NOMINAL VARIABLE on a QUANTITATIVE VARIABLE. If the means are different, this must be due to the effect of some variable.

The key to the understanding of analysis of variance lies in the fact that the observations on the dependent variable are different from each other. If the observations were all the same, then there could not be any effects of any variables. If the nominal, independent variable were the only variable that had any effect on the DEPENDENT VARIABLE, then the observations in each group would be identical. If gender were the only variable that affected income, then all women would have the same income and all men would have the same income, which would be different from the income of the women. This can be simplified by saying that all women would have an income equal to the mean income of women, and all the men would have an income equal to the mean income for men.

But most of the time, the observed values of the dependent variable are different from each other and different from the mean for the group. The fact that not all women have the same income implies that there is one or more variables, other than gender, that also have an effect on income. Thus, it is the VARIATION in the observations within a group that tells us that there are effects of other variables present in the data. Furthermore, it is the magnitude of the variations that tell us whether the effects are small or large.

Next, how can we measure the magnitude of the variations of the observations within a group? One possibility is to see how much each observation deviates from the mean in the group, square the deviation from the mean, and then add the squares. For example, if the observations in a particular group equal 7, 9, 10, and 14, then the mean equals 10. The deviations from the mean become -3 , -1 , 0 , and 4 ; the squares of these numbers are 9 , 1 , 0 , and 16 ; and the sum of these squares equals 26 . That is the magnitude of the variation of the observations within this particular group, as measured by a sum of squares.

Next, we find the magnitudes of the variations in each group and add all these sums of squares across the groups. This sum is known as the within-sample sum of squares. It is also called just the within-group sum of squares, or simply the within sum of squares, or the error sum of squares. Because the variations within the groups are due to all variables other than the nominal variable that defines the groups, the sum of squares is also better known as the residual sum of squares.

The reasons for using squares, and not some other method, are mainly historical and mathematical.

WITHIN-SUBJECT DESIGN

Before common availability of statistical software, EXPERIMENTAL DESIGNS were developed with ease of computations in mind. Definitional formulas were hard to use, and efforts were made to simplify the necessary computations. But that made it difficult to see similarities between designs. Within-subject analysis is very similar to REPEATED-MEASURES DESIGNS. Both can now be handled in their simplest case as a two-way ANALYSIS OF VARIANCE with one observation per cell.

The within-subject design is used for taking measurements under different conditions, such as test scores, from several subjects. The question is whether there is any change in these measurements. Change implies that the variation in the scores for the subjects due to the different conditions is larger than what can be expected from randomness alone.

We assess the overall variation in the measurements for a single subject by finding the mean value for the subject, subtracting this mean from each measurement, squaring the differences, and adding the squares. This gives the variability in the scores *within* a particular subject, thus the name of the design. After finding the within SUM OF SQUARES for each subject, we add these sums to get the overall within-subject variation. In symbols, the within-subject sum of squares equals

$$\sum \sum (y_{ij} - \bar{y}_i)^2,$$

where y_{ij} is the j th measurement on the i th subject and from which we subtract the mean for the i th subject. The summation is across all conditions and all subjects. With k measurements on each subject, the within sum of squares for a subject has $k - 1$ DEGREES OF FREEDOM. With data on n individuals, the within-subject sum of squares above has $n(k - 1)$ degrees of freedom.

There are two reasons for the within-subject variation. One is attributed to the effect of the different conditions. The other is attributed to the residual variable.

The value of the residual variable for the j th measurement on the i th subject is found from the following expression:

$$\begin{aligned} (y_{ij} - \bar{y}) - (\bar{y}_i - \bar{y}) - (\bar{y}_j - \bar{y}) \\ = y_{ij} - \bar{y}_i - \bar{y}_j + \bar{y}. \end{aligned}$$

From the deviation of the measurement from the overall mean, subtract the effect of the subject (subject mean minus overall mean) and the effect of the particular condition (condition mean minus overall mean). After taking out these two effects, whatever is left is the effect of the residual variable. (We recognize the resulting expression as the interaction effect in a two-way analysis of variance, used as the residual effect when there is only one observation per cell.) The residual sum of squares has $(n - 1)(k - 1)$ degrees of freedom.

The sum of squares for the different conditions can now be found as the difference between the within-subject sum of squares and the RESIDUAL SUM OF

SQUARES. The degrees of freedom for this difference equals $n(k - 1) - (n - 1)(k - 1) = k - 1$.

If the condition sum of squares is large, then there has been a change in the measurements from one condition to the next. We assess the magnitude of this sum of squares by comparing its mean square with the residual mean square, resulting in a value of the F variable and thereby a p value.

WRITING

Like all language, writing is a constitutive force that creates a particular view of reality and inscribes particular values. Styles of writing reflect historically shifting paradigms; social scientific writing, like all other writing, is a sociohistorical construction, neither immutable nor dispassionate. Writing in the social sciences is a site of contestation. How one writes, what one writes, and for whom one writes are theoretical, ethical, and methodological issues, sometimes referred to as “the crisis in representation” (Clifford & Marcus, 1986).

HISTORICAL DEVELOPMENT

Beginning in the 17th century, the Western world of writing was divided into two kinds: literary and scientific. Literature was associated with fiction, rhetoric, subjectivity, and an ambiguous (interpretive) voice, whereas science was associated with fact, truth, objectivity, and an unambiguous voice. During the 18th century, assaults against literary writing grew severe. Jeremy Bentham proposed that the ideal language would have no words, only symbols; David Hume described poets as professional liars; and Samuel Johnson sought, through his dictionary, to fix the meanings of words in perpetuity. Into this linguistic world, the Marquis de Condorcet introduced the term

social science, contending that if a precise language about moral and social issues were adopted, erroneous thought and action would be almost impossible. By the 19th century, literature and science stood as two separate domains. Literature was aligned with “art” and “culture,” containing the values of taste, aesthetics, ethics, humanity, and morality, whereas science was aligned with precision and objectivity. Because science’s status was greater than that of literature, some literary writers attempted to make literature a part of science. By the late 19th century, “realism” dominated both scientific and fiction writing, the latter spearheaded by Honore de Balzac and Emile Zola.

As the 20th century unfolded, the relationship between social scientific writing and literary writing grew more complex. The demarcations between “fact/fiction,” “subjective/objective,” and “true/imagined” blurred. The “New Journalists” made themselves the subjects of their writing; English departments positioned novels by minorities and postcolonials as “ethnographic fiction”; and social scientists, troubled by the “crisis in representation,” began publishing their research in literary formats—poetry, stories, and dramas (see CREATIVE ANALYTICAL PRACTICE ETHNOGRAPHY). In the 1970s, the crossovers spawned oxymoronic genres: “creative nonfiction,” “faction,” “ethnographic drama,” and “true novel,” to name a few. In the 1980s, John Van Maanen (1988) identified three kinds of ETHNOGRAPHIC TALES—realist, confessional, and impressionistic. By 1990, within social science, the schism between those who adhered to the scientific model of writing and those who chose to supplement that model with tools from the literary world widened. The schism shows no signs of narrowing.

Most of the social scientists who have expressly chosen literary tools are QUALITATIVE RESEARCHERS. Unlike quantitative researchers, who can express their findings in tables and charts, qualitative researchers must depend upon words. Because a goal of contemporary qualitative research is to bring to life for the reader the world studied in all its complexities, literary tools (e.g., scene setting, dialogue, multiple points of view, tone) and formats (essay, poetry, letter, dialogues, etc.) other than the research paper’s conventions and format have proved helpful.

Although most qualitative researchers purposefully choose literary devices, some continue to write within the general conventions of social science. Many of these view writing simply as a “mopping-up” activity,

“deskwork” following the real work or “fieldwork.” They are committed to the science model, and many have turned to computer programs for help in analyzing their data. But, increasingly, qualitative researchers are defining writing itself as a way of “knowing”—not just “telling”—a method of discovery, inquiry, and analysis.

WRITING AS METHOD OF INQUIRY

Writing as a method of inquiry departs from standard social scientific practices. It offers an additional—or alternative—research practice. The goal of writing as a method of discovery is to learn new things about one’s project, one’s self, and the relationship between the two. With this goal in mind, writers explore different writing formats, voices, points of view, and tones. In some ways similar to a free-ranging conversation with a trusted friend, a conversation without a preconceived notion of its outcome, this writing exploration creates the conditions for new insights—insights that would not occur if one followed the canonical format.

Writing as method of discovery further coheres with the core of POSTSTRUCTURALISM, namely, the *doubt* that any one theory or method, discourse or genre, tradition or novelty has a universal and general claim to authoritative knowledge. Rather, poststructuralism encourages claims to local, historical, and partial knowledge. That knowledge, moreover, shifts depending upon the voice, format, tone, and so on of one’s writing, along with shifts in one’s life contexts. Knowing about one’s research and knowing about oneself are inextricably intertwined, and unavoidably partial knowledges. Self and social science are “twin-born.”

Poststructuralism supports three writing strategies. First, the writing “I” that is always present, whether acknowledged or not, should be reflexively explored and inquired into by the writer. The writer asks, for example, “Why am I writing this text? What are my power interests?” Second, because one’s subjectivity—the writing “I”—is created in a context of competing discourses and local squabbles,

one’s subjectivity is neither fixed nor rigid, but shifts. Consequently, what one writes is not immune to the writer’s life situations. Writers are encouraged to contextualize their research in other frames, such as disciplinary, departmental, and familial relationships (see Richardson, 1997). Third, because knowledge is partial, the writer cannot say everything in one text, in one voice, in one format. Rather, the writer is encouraged to explore the material, shape it and cut it, from multiple points of view and in different formats. Examples of multiple takes on ethnographic materials are: *Composing Ethnography: Alternative Forms of Qualitative Writing*, edited by Carolyn Ellis and Arthur P. Bochner; *Troubling the Angels: Women Living With HIV/AIDS*, by Patti Lather and Christine Smithies; *Reading Auschwitz*, by Mary D. Langerwey; *Tales of the Field: On Writing Ethnography*, by John Van Maanen; *Travels with Ernest: Crossing the Literary-Ethnographic Divide* by Laurel Richardson and Ernest Lockridge; and *A Thrice Told Tale: Feminism, Postmodernism and Ethnographic Responsibility*, by Margery Wolf. In that book, Wolf tells about her research in Taiwan through a fictionalized story, her field notes, and a traditional social science article.

X

X VARIABLE

An INDEPENDENT VARIABLE in REGRESSION analysis is termed an X variable because it is usually depicted graphically along the horizontal axis (“ x -axis”) of a SCATTERPLOT. It is sometimes termed a right-side variable, in that it appears on the right-hand side of the regression equation. The X variable represents the presumed cause in a cause-and-effect relationship, whereas the Y variable denotes the effect.

Take a standard regression equation of the form $Y = a + bX$. The X on the right-hand side of the equation represents an independent variable. Consider an analysis of the effect of population density on crime rates in cities. The population density would be the X variable, which might be found to affect the crime rate, the DEPENDENT VARIABLE.

Similarly, in a DIFFERENCE OF MEANS test, the X variable is the DICHOTOMOUS VARIABLE for which the mean of the dependent variable is calculated. In looking to see whether men and women differ significantly in their vote turnout, for example, gender is the X variable. The turnout rates of men and women would be calculated, and then a DIFFERENCE-OF-MEANS test would be used to check whether that difference is statistically significant.

Generalizing to CROSS-TABULATIONS, percentages generally are taken within categories of the X variable, with comparisons made across categories of the X variable in order to gauge the effect of the independent variable on the dependent variable. In comparing the rates of church attendance of different religious denominations, for example, denomination would be

the X variable. The proportion of Catholics who go to church regularly might be compared to the proportion of Protestants and to the proportion of adherents of other religions who go to religious services regularly.

—Herbert F. Weisberg

$\bar{X}$

$\bar{X}$ is the notation for the arithmetic MEAN of a VARIABLE. If the variable is denoted by X , the i th observation’s value on variable X is denoted by X_i , and N is the total number of observations, then $\bar{X} = \sum X_i / N$. Figure 1 shows a density plot of spending on elementary and secondary education in the 50 American states, with the mean indicated on the graph.

The MEAN is most appropriate as a MEASURE OF CENTRAL TENDENCY when the data are NUMERIC, though the MEDIAN might be more appropriate when there are OUTLIERS on the variable. The mean also can be computed for DICHOTOMOUS VARIABLES (scored as either “1” or “0”), in which case the mean is simply the proportion of cases in the “1” category. The mean is also often computed for ORDINAL MEASURES, though that use is debatable. For example, Gravetter and Wallnau (2000) argued against calculating the mean and other traditional statistics with ordinal variables because the distance between values, and hence the mean, is not well defined. However, Borgatta and Bohrnstedt (1980) instead argued that there are latent CONTINUOUS VARIABLES underlying ordinal variables, so results obtained with integer scoring would be fairly

Figure 1 Density Plot With Mean Identified

SOURCE: State Politics & Policy Quarterly Data Resource at <http://www.unl.edu/sppq>

close to those that would be obtained for the true unknown numbered categories.

$\bar{X}$ has several distinctive properties leading to interpretations of the mean. First, the sum of signed DEVIATIONS around the mean is zero. That is $\sum (X_i - \bar{X}) = 0$. Furthermore, the sum of signed deviations around any value other than the mean is larger. As a result, the mean is considered a “best guess” statistic, in that guessing that the value of an observation is the mean leads to a smaller total error than would any other guess.

Second, the sum of positive deviations from the mean equals the sum of negative deviations from the mean (which is why the sum of signed deviations

around the mean is zero). Because of that property, the mean is sometimes described as the fulcrum (or balance point) of the variable’s distribution. To the extent that some values are above $\bar{X}$, they are balanced off by other values below $\bar{X}$.

Third, the sum of squared deviations around $\bar{X}$ is smaller than the sum of squared DEVIATIONS around any other value. This LEAST-SQUARES property of the mean is why VARIANCES are computed around the mean.

Additionally, $\bar{X}$ is a consistent, UNBIASED, and efficient estimator of the variable’s POPULATION mean. It is consistent because the probability that $\bar{X}$ minus the population mean is less than any value (δ) approaches 1 as the number of observations becomes infinitely large. It is unbiased because its expectation

is the population mean. $\bar{X}$ is considered efficient because the variance of SAMPLE means around their mean is smaller than it would be for any other estimator of the population mean.

Y

Y-INTERCEPT

In a SIMPLE REGRESSION model, the y-intercept is the expected value of the DEPENDENT VARIABLE when the INDEPENDENT VARIABLE equals zero. In the regression equation $Y = a + bX$, a is the y-intercept. Visually, in a two-dimensional SCATTER PLOT with a regression line, the y-intercept is the value of y where the regression line crosses the vertical axis. In a MULTIPLE REGRESSION model, the intercept is the expected value of the dependent variable when all independent variables equal zero.

Consider the following example, in which a researcher is interested in factors that reduce heart disease, or at least reduce the most harmful effects of heart disease. In particular, this researcher wants to examine the RELATIONSHIP between wine consumption (X VARIABLE) and deaths from heart disease (Y VARIABLE). The main HYPOTHESIS is that increased wine consumption may lower the risks of heart disease. The researcher gathers data on annual wine consumption (liters per person) and heart disease deaths (per 100,000 population) from several countries. The estimated regression model from the data is $Y = 261 - 23X$. In this example, the y-intercept is 261, indicating that in a hypothetical country with no wine

consumption, the model predicts 261 deaths from heart disease for every 100,000 people in the country. The data are plotted in Figure 1 below, with the regression line included. The value of the y-intercept is noted in the figure.

Because $Y = a$ when $X = 0$, the y-intercept is also called the “constant” in the regression equation. In some substantive situations, the researcher may decide for theoretical reasons that the dependent variable should always be zero when the independent variable is zero. In that case, the regression equation can be calculated with no constant (so that a is zero), and the simple

Figure 1 Scatterplot With y-Intercept Identified

SOURCE: Moore (1998), p. 314.

regression equation becomes $Y = bX$. Graphically, this would correspond to a regression line through the origin.

Y VARIABLE

The Y variable in regression analysis is the **DEPENDENT VARIABLE**, so named because it is conventionally depicted as the vertical (y) axis in a **SCATTERPLOT** showing the **RELATIONSHIP** between two variables. The Y variable represents the effect or outcome in a cause-and-effect relationship, whereas X usually denotes the cause or **INDEPENDENT VARIABLE**. The Y variable is generally shown on the left-hand side of regression equations; therefore, it is sometimes referred to as a left-side variable. For example, a **SIMPLE REGRESSION** equation is often written as $Y = a + bX + e$. Figure 1 shows a hypothetical relationship between years of education and income, where income is the Y variable because it is

Figure 1 Scatterplot With Y Variable Identified

presumed to be affected by how many years of education a person has.

In **CROSS-TABULATIONS** of two variables, percentages are generally computed to determine the percentage of a given independent variable category that falls into each category on the dependent Y variable. In **DIFFERENCE-OF-MEANS** tests, the **MEAN** on the Y variable is computed within each category of the **PREDICTOR VARIABLE**, with a **SIGNIFICANCE TEST** to determine whether the obtained difference between the Y variable means is larger than expected on the basis of chance.

For example, in determining the relative contributions of different factors to a car's gas mileage, its miles per gallon would be the Y variable, whereas its weight, number of engine cylinders, and age might be plausible predictor variables. In this case, the **MULTIPLE REGRESSION** model could be written as $Y = a + bX + cW + dZ + e$, where Y represents the dependent variable (gas mileage) and X , W , and Z represent the predictor variables.

—David C. Kimball and Herbert F. Weisberg

YATES' CORRECTION

An adjustment used in connection with the **CHI-SQUARE** statistic. It is usually employed in connection with 2×2 **CONTINGENCY TABLES** and is sometimes used to improve the accuracy of tables with small **CELL** frequencies. It is used less frequently than in the past because of concerns that it may actually increase the chances of making a **TYPE II ERROR**. Essentially, the correction results in a smaller chi-square value and therefore a more conservative approach to chi-square, because it makes **STATISTICAL SIGNIFICANCE** more difficult to establish.

—Alan Bryman

YULE'S Q

A measure of **ASSOCIATION** used to indicate the strength of relationship between dichotomous variables at nominal or higher level. Yule's Q is also a

function of the ODDS RATIO standardized to fall between -1 and $+1$. To obtain Yule's Q from the odds ratio (OR) (Walsh & Ollenburger, 2001):

$$Q = (OR - 1)/(OR + 1).$$

Table 1 illustrates using Q with hypothetical social science data. In this example, the independent variable is gender and the dependent variable is political party. A working hypothesis from these data is that males are more likely to be Republicans than are females. Q is calculated from the cell frequencies in Table 1 using the odds ratio in the following manner:

$$OR = ad/bc,$$

$$OR = (10 \times 12)/(2 \times 4) = 120/8 = 15.$$

Q is then calculated as follows:

$$Q = (15 - 1)/(15 + 1) = 14/16 = .875.$$

Q is also calculated by finding the difference between concordant (P) and discordant (Q) pairs of data and dividing by the total of the concordant and discordant pairs. Tied pairs of data are excluded from the calculation. The number calculated from this method is the overall percentage of the concordant/discordant pairs and is also equal to the result calculated by the odds ratio method. The concordant/discordant formula for Q (Garson, 2002) is the following:

$$Q = (P - Q)/(P + Q).$$

Data pairs are concordant when moving from the first datum to the second involves a shift in the values of the independent variable and a shift in the values of the dependent variable consistent with the hypothesis being considered. Discordant pairs also involve shifts in value but ones inconsistent with the hypothesis. Tied data pairs share the same value of the dependent variable and are not part of the calculation.

$$Q = (ad - bc)/(ad + bc),$$

$$Q = [(10 \times 12) - (2 \times 4)]/[(10 \times 12) + (2 \times 4)],$$

$$Q = .875.$$

The results from these data indicate that there is a strong association between the variables in the data

Table 1 The Relationship of Gender to Choice of Political Party

	Male	Female
Republican	$a = 10$	$b = 2$
Democrat	$c = 4$	$d = 12$

set. Because the variables in this case are nominal, the sign of .875 is the result of the ordering of the variables. Reversing the order reverses the sign, but the magnitude of association remains the same. Q is a symmetric measure; it makes no difference which variable is chosen as the independent variable.

Q is interpreted as a proportionate reduction of error (PRE); for example, knowing someone's gender reduces our error in predicting the rank of the dependent variable by 87.5%. In other words, by knowing that a subject is male, one may guess the party affiliation is Republican and have a strong chance of being correct and supporting the working hypothesis. In the event Q equals 0, the relationship is statistically independent, so knowledge of the second variable is not helpful.

There is a note of caution in using Q . It is important to understand the distribution of the data and not rely totally on the measure itself. If any one of the frequency cells is 0, then calculating Q indicates there is a perfect relationship (White, 1999). Calculating Q from Table 2 in the same manner as before,

$$Q = [(10 \times 0) - (2 \times 4)]/[(10 \times 0) + (2 \times 4)],$$

$$Q = -1.0.$$

A perfect association of -1.0 is misleading in this particular case with only two female respondents in the data set.

Q is usually reported as GAMMA because there is a special application of it for 2×2 contingency tables. However, the value of Q is usually lower than gamma

Table 2 The Relationship of Gender to Choice of Political Party

	Male	Female
Republican	$a = 10$	$b = 2$
Democrat	$c = 4$	$d = 0$

because dichotomized data contribute to data loss and attenuation of the strength of association.

Z

Z-SCORE

A z -score is obtained by subtracting the MEAN from the value of a variable and then dividing the result by its STANDARD DEVIATION. Such a standardized score is the number of standard deviations that the value of a case is removed from the mean. It shows the relative status of that score in a DISTRIBUTION.

In social science research, we often replace original measurement scores by new ones, a procedure that is called TRANSFORMATION. The original scores are called *raw scores*, the new ones *transformed scores*. We may denote these as x and x' , respectively. If the transformation is linear, so that $x' = ax + b$, then it holds for the mean as well as the standard deviation that there will be a fixed relationship between the original value and the transformed value. For the mean, $\bar{x}' = a\bar{x} + b$, and for the standard deviation, $s_{x'} = as_x$. It follows that $a = s_{x'}/s_x$ and $b = \bar{x}' - a\bar{x} = \bar{x}' - (s_{x'}/s_x)\bar{x}$. Hence, the transformed scores can be written as $x' = ax + b = (s_{x'}/s_x)x + \bar{x}' - (s_{x'}/s_x)\bar{x} = (s_{x'}/s_x)(x - \bar{x}) + \bar{x}'$. In this formula, the mean and the standard deviation of the raw scores ($\bar{x}$ and s_x) are known from the data. Before transformation, we have to decide what the mean and standard deviation of the transformed scores will be. A popular choice is $\bar{x}' = 0$ and $s_{x'} = 1$. Then, the transformed score becomes $x' = (s_{x'}/s_x)(x - \bar{x}) + \bar{x}' = (1/s_x)(x - \bar{x}) + 0 = (x - \bar{x})/s_x$. This transformed score is known as the *standardized score* or *z -score*, and the transformation is called *z -transformation*: $z = (x - \bar{x})/s_x$. If we deal with the POPULATION instead of the sample, then Greek instead of Latin letters are used, so that $z = (x - \mu)/\sigma$.

AN EXAMPLE

Suppose you are studying the sleeping behavior of students, and you are told that François sleeps 10 hours per night. This score gives quite a different picture when the mean is 8 and the standard deviation is 2 than it does when the mean is 12 and the standard deviation is 4. In the first distribution, it is $z = (10 - 8)/2 = 1$, which means that François sleeps 1 standard deviation more than the mean, and in the second distribution, it is $z = (10 - 12)/4 = -0.5$, which means that he sleeps half a standard deviation less than the mean. So, he would be a sleepyhead in one distribution but a light sleeper in the other.

STANDARDIZATION OR NOT?

Standardization is useful because it leads to new sets of scores that are comparable. For example, the scores on two psychological tests will seldom be comparable. Changing to standardized scores permits comparison, so that it can be decided whether a person's performance on one test is better or worse than his performance on another. However, on the other hand, standardization is a procedure in which the variance of variables is artificially forced to be unity in order to obtain comparability, and it might be argued that this is too drastic an operation, because the score of an individual—for example, the educational level of François—has different meanings in societies with different amounts of educational variation. In this situation, nonstandardized scores (with indication of the standard deviation) might be preferred.

In general, standardized scores should be used when comparability is needed of many variables in one and

the same statistical model, and not used if the objective is to compare one or more variables of a statistical model in different samples. When we do not standardize, we must report the standard deviations of the variables.

OTHER WAYS OF ENSURING COMPARABILITY

A final remark is that standardization is but one way of expressing scores on different variables so as to have comparability. Another way would be the transformation to PERCENTILES.

It should also be noted that, in all the examples given above, variables were assumed to follow approximately a NORMAL DISTRIBUTION. For skew distributions and for comparison of variables with distributions of unequal form, the z -score becomes less valid as an indicator of the relative position of a variable in a distribution. In such cases, the nonnormal (e.g., skewed) distributions are transformed into a normal distribution. The transformation is then NORMALIZATION instead of linearization.

Z-TEST

The z -test uses Z-SCORES to conduct SIGNIFICANCE TESTING for large samples. There are a number of significance tests in which the SAMPLING DISTRIBUTION has the form of the normal PROBABILITY DENSITY FUNCTION, which is then transformed into the standardized normal probability density function, so that the test scores become z -scores. A simple example is the test about a population mean such as a mean IQ score. If the NULL HYPOTHESIS states that the mean is 100 ($H_0 : \mu = 100$), then this is an exact hypothesis. If it states that the mean is at most 100 ($H_0 : \mu \leq 100$),

then it is an inexact hypothesis. The alternative hypothesis for the latter case could be that the mean is greater than 100 ($H_a : \mu > 100$). The test would then be one-tailed, because we hypothesize that the people of our sample are more intelligent than 100 on the average. For the two-tailed test, the alternative hypothesis would be $H_a : \mu \neq 100$. It is common to combine an inexact alternative hypothesis with an exact null hypothesis. For example, the alternative hypothesis that the mean IQ of a population is more than 100 ($H_a : \mu > 100$) is tested against the null hypothesis that the mean is equal to 100 ($H_0 : \mu = 100$).

Z-TEST OF A SINGLE MEAN

The z -test will be performed by evaluating the ratio $(\bar{x} - \mu) / \sigma_{\bar{x}}$ —where $\bar{x}$ is the sample MEAN, μ is the population mean under H_0 , and $\sigma_{\bar{x}}$ is the STANDARD ERROR of the mean (STANDARD DEVIATION of the sampling distribution of means under H_0)—when we are interested in testing the foregoing hypothesis about the mean IQ of the population. This ratio transforms a mean deviation into a z -score. Now suppose that in a sample of $n = 900$, randomly drawn with replacement, $\bar{x} = 102$ and $s = 10$. The sample is large enough, according to the CENTRAL LIMIT THEOREM, so the sampling distribution should be normal with mean equal to the population mean μ and variance $\sigma_{\bar{x}} = \sigma^2 / n$. Because σ is unknown, the variance of the sampling distribution will be estimated as $\hat{\sigma}_{\bar{x}}^2 = s^2 / n$ (instead of σ^2 / n), and its square root gives $\hat{\sigma}_{\bar{x}}$. Our sample result, $\bar{x} = 102$, is subsumed under the sampling distribution with mean 100 and variance $s^2 / n = 10^2 / 900 = 0.111$. Its z -score is then $z = (102 - 100) / \sqrt{0.111} = 6$. For this value of z or higher, we find in the standardized normal table a probability of 0.000001, which is so small (much smaller than a probability of making a TYPE I ERROR of $\alpha = .05$ or even of $\alpha = .001$) that it is highly unlikely to find this sample result under the null hypothesis. Hence, the null hypothesis is rejected, and we have found empirical support for the alternative hypothesis that $\mu > 100$. We may mention here that we do not know what the probability of TYPE II ERROR β is, but with a sample of large size ($n = 900$), we can be confident that β will be small.

OTHER APPLICATIONS OF THE Z-TEST

The z -test has many other applications. One is the test of a proportion. With presidential elections, the

proportion for determining winning is often $\pi = 0.50$. So, let us test the hypothesis that a candidate has more than half of the votes, that is, $H_a : \pi > 0.50$. This will be tested against the null hypothesis $H_0 : \pi = 0.50$. The proportion in the population is now indicated with the Greek letter π , and in the sample with the Latin letter p . The sampling distribution will now be a distribution of proportions (instead of means), given that the null hypothesis would be true. This sampling distribution has now the form of a BINOMIAL distribution. For large samples, it holds again that the NORMAL DISTRIBUTION can be used instead, because the binomial and normal probabilities then become identical. The mean of this sampling distribution of proportions is the population proportion π (under the null hypothesis), and its variance is $\pi(1 - \pi)/n$, where n is the sample size. Now suppose that in a sample of $n = 900$ before the elections, randomly drawn with replacement, we found $p = 53\%$ intended votes for the candidate. The sampling distribution of proportions, given a large sample, has the form of a normal distribution with mean $\pi = 0.50$ and variance $\pi(1 - \pi)/n = (0.50)(0.50)/900 = 0.0002777$. It then follows that $z = (p - \pi)/\sqrt{\pi(1 - \pi)/n} = (0.53 - 0.50)/\sqrt{0.0002777} = 1.8$. For this value of z or higher, we find in the standardized normal table a probability of .0359, which is smaller than $\alpha = .05$, so that it is highly unlikely we would find this sample result under the null hypothesis. Hence, with a likelihood of $1 - \alpha = 0.95$, the null hypothesis is rejected, and we have found empirical support for the alternative hypothesis that the candidate's votes should be significantly higher than 50%.

One remark of caution must be made. The binomial, a discrete distribution, is approximated here by the continuous normal distribution. Therefore, a value of p is, in fact, the midpoint of an interval, and a "correction for continuity" has to be made. In calculating the z -score, we subtract $0.5/n$ from p if p happens to be greater than π , and we add $0.5/n$ to p if p happens to be smaller than π . For our example, the z -score of the sample proportion p becomes $z = [p - (0.5/n) - \pi]/\sqrt{\pi(1 - \pi)/n} = [0.53 - (0.5/900) - 0.50]/\sqrt{0.0002777} = 1.767$, as opposed to the value of 1.8 obtained previously. The correction is rather small because of the large sample size. In general, the correction for continuity should be used especially when the sample size is small.
